PREFACE

THE greater part of this volume is devoted to the silicates which, in turn, are closely connected with mineralogy. In the original design of this work—many years backwards—it was not intended to devote so much space to the minerals, but no sound reason could be found for excluding the purer minerals from inorganic chemistry. It is merely an *accidental* circumstance that the majority of the silicates has been made in Nature's laboratory where she is continually carrying on an endless variety of chemical operations, the results of which, like those which obtain in our own laboratories, belong to the domain of chemistry. No one doubts that the minerals have been formed by the operations of the very same laws as those which are recognized in general chemistry. On its chemical side, therefore, mineralogy is a subordinate branch of inorganic chemistry.

In many of the legal cases tried in the courts in connection with the so-called "mineral rights," it has been instructive to see how difficult it has been to get a definition of a mineral which can hold its own against the cross-examination of the opposing counsel. Those accustomed to declaim only before passive listeners-in are sometimes bewildered by the conflict of testimony which is more or less dominated by training, temperament, interests, and desires. From the chemical side, the definition is neither more nor less difficult than is the definition of a chemical compound discussed in the second chapter of this work.

An appalling number of analyses have been reported for many minerals. As a result, the chemist can regard most minerals only as more or less "dirty compounds." To continue the language of the laboratory, Nature has used dirty beakers and dirty solvents in the production of minerals, and she has not always preserved her products from contamination after they have been made. These "dirty compounds" have often received different names, and even different names with different degrees of contamination. It is therefore a problem for the mineralogist to select a kind of representative or idealized mineral from a mass of analyses of contaminated products.

The difficulties which have attended the efforts to find the essential composition of a mineral have been accentuated when the attempt has been made to elucidate its constitution. In particular cases, owing to the paucity of relevant facts, quite a number of opposing hypotheses has been defended. There is a temptation to solve or perhaps evade many of the difficult problems by regarding the untractable minerals as solid solutions of a number of simpler components. So long as the constitution of a mineral has not been completely elucidated, it is better to employ the mineralogist's term in place of a systematic name; otherwise, as in the case of some compounds in organic chemistry, the name adopted will depend on the particular hypothesis which happens to be in fashion at the time. I cannot help taking the opportunity of expressing my appreciation of the valuable work being done under Dr. A. L. Day at the Geophysical Laboratory, Carnegie Institution of Washington. Here a good start has been made in introducing order in the mineralogical chaos.

The chapter on carbon does not include those hydrocarbons, and their derivatives commonly but arbitrarily admitted into inorganic chemistry, the cyanides and

PREFACE .

complex cyanides; nor does it include the combustion of the hydrocarbons. These subjects may later be discussed in a supplementary volume.

I greatly appreciate the kindness of my colleagues—Dr. A. Scott, Mr. H. V. Thompson, and Mr. A. T. Green—who have read the proofs of this and the previous volumes; of Mr. A. Rigby, who has also read all the volumes; of Mr. F. H. Clews, who has read from Vol. III; of Mr. L. S. Theobald, from Vol. IV, and of Mr. A. J. Dale, from Vol. V.

I W. M.

CONTENTS

CHAPTER XXXIX (continued)

CARBON (continued)

§ 80. The History of Carbon Dioxide (1); § 81. The Occurrence of Carbon Dioxide (2); § 82. The Metabolism of Animals and Plants (10); § 83. The Formation and Preparation of Carbon Dioxide (15); § 84. The Physical Properties of Carbon Dioxide (19); § 85. The Solubility of Carbon Dioxide (47); § 86. The Chemical Properties of Carbon Dioxide (61); § 87. Hard and Soft Water (78); § 88. Percarbonic Acid and the Percarbonates (82); § 89. The Sulphides of Carbon (87); § 40. The History, Occurrence, and Preparation of Carbon Disulphide (94); § 41. The Physical Properties of Carbon Disulphide (96); § 42. The Chemical Properties of Carbon Disulphide (106); § 43. The Thiocarbonic Acids and the Thiocarbonates (119); § 44. Perthiocarbonates (180); § 45. The Thiocarbamic Acids and the Thiocarbamates (182).

the cross references the first number in clarendon type is the number of the volume; the second number refers to the chapter; and the succeeding number refers to the "§," section. Thus 5. 88, 24 refers to § 24, chapter 88, volume 5.

The oxides, hydrides, halides, sulphides, sulphates, carbonates, nitrates, and phosphates are considered with the basic elements; the other compounds are taken in connection with the acidic element. The double or complex salts in connection with a given element include those associated with elements previously discussed. The carbides, silicides, titanides, phosphides, arsenides, etc., are considered in connection with carbon, silicon, titanium, etc. The intermetallic compounds of a given element include those associated with elements previously considered.

The use of triangular diagrams for representing the properties of three-component systems was suggested by G. G. Stokes (*Proc. Roy. Soc.*, 42, 174, 1891). The method was immediately taken up in many directions and it has proved of great value. With practice it becomes as useful for representing the properties of ternary mixtures as squared paper is for binary mixtures. The principle of triangular diagrams is based on the fact that in an equilateral triangle the sum of the perpendicular distances of any point from the three sides is a constant. Given any three substances *A*, *B*, and *C*, the composition of any possible combination of these can be represented by a point in or on the triangle. The apices of the

ABBREVIATIONS

triangle represent the single components A, B, and C; the sides of the triangle represent binary mixtures of A and B, B and C, or C and A; and points within the triangle ternary mixture. The compositions of the mixtures can be represented in percentages, or referred to unity, 10, etc. In Fig. 1, pure A will be represented by a point at the apex marked A. If 100 be the

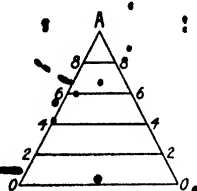

FIG. 1.

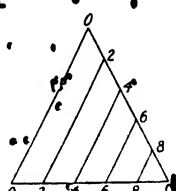

FIG. 2.

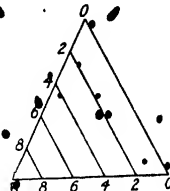

FIG. 3.

standard of reference, the point A represents 100 per cent. of A and nothing else; mixtures containing 80 per cent. of A are represented by a point on the line 88, 60 per cent. of A by a point on the line 66, etc. Similarly with B and C. Figs. 3 and 2 respectively. Combine Figs. 1, 2, and 3 into one diagram by superposition, and Fig. 4 results. Any point in this

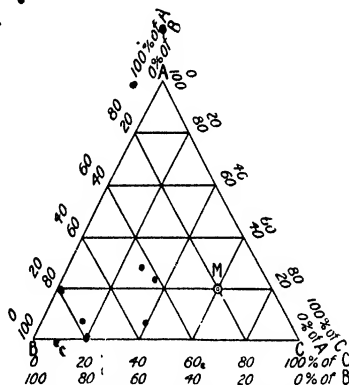

FIG. 4.—Standard Reference. Triangle.

diagram, Fig. 4, thus represents a ternary mixture. For instance, the point M represents a mixture containing 20 per cent. of A, 20 per cent. of B, and 60 per cent. of C.

CHAPTER XXXIX (continued)

CARBON (continued)

§ 30. The History of Carbon Dioxide

In the first century of our era Pliny¹ mentioned the exhalation of lethal vapours—*spiritus lethales*—from caverns, like the Grotto del Cane, etc. It was also known that the mild alkalies gave off a gas with effervescence when treated with acetic acid or vinegar—*vide* 2. 20, 1. No one, however, recognized that these phenomena were produced by specific gases. A. Libavius, in 1597, also noted the acidic qualities of certain mineral waters which he attributed to the presence of an imponderable *spiritus* of great volatility. Shortly afterwards, J. B. van Helmont, who had *l'immortelle gloire de révéler scientifiquement l'existence de corps invisibles et impalpables—les gaz*, pointed out that:

Carbon, and, in general, bodies which cannot be immediately resolved into water necessarily give off, during combustion, *spiritus sylvestris*—*vide* 1. 3, 1. Sixty-two parts of oak-charcoal leave one part of ash, and the remaining sixty-one parts produce the *spiritus sylvestris*.

In addition to the formation of *gas sylvestre* (i) by the combustion of carbon, and (ii) during fermentations, J. B. van Helmont showed that (iii) it is also formed when calcareous stones are treated with distilled vinegar; and (iv) it is found in the air of caverns, mines, and cellars. (v) Mineral waters like those of Spa disengage the gas sylvestre when exposed to the air; and (vi) the flatus produced by the digestion of food and by the excrement is gas sylvestre: J. B. van Helmont called gas sylvestre many names—*gas carbonum*, *gas vinorum*, *gas uvarum*, *gas musti*, etc. C. Wren, and J. Bernoulli made some confirmatory observations, and F. Hoffmann in his work on mineral waters often alludes to this gas as the *principium spirituosum*, *spiritus mineralis*, and less frequently as the *spiritus sulphureus*, *spiritus athereus*, and *spiritus elasticus*. He discovered that when charcoal is burnt it dissolves in the atmosphere producing choke-damp; and he noted that like acids, the soln. of the gas in water reddens blue-coloured extracts of plants. The subject was discussed by F. Vengl, J. F. Demachy, etc. R. Boyle noted the evolution of an air—*factitious air*—when corals or oyster shells are treated with vinegar, and in fermentations. S. Hales made some observations on this gas in 1727; H. Boerhaave, in 1732, emphasized the suffocating effects of gas sylvestre, although this quality had been noted by J. B. van Helmont.

J. Black's work in 1757 on the mild and caustic alkalies—i.e. alkali carbonates and hydroxides—showed that the causticity of quicklime was not due to the union of phlogiston with elemental chalk, but rather is chalk produced by the union of quicklime with what J. Black called *fixed air*—*vide* 2: 20; 11. In 1764, D. McBride studied the formation of fixed air in fermentation and putrefaction, and its presence in blood, and in atm. air. In 1766, H. Cavendish made a number of observations on fixed air, and found that fixed air precipitates chalk from a soln. of lime-water, and that the precipitate is redissolved by the continued action of fixed air. T. Lane also examined the action of an eq. soln. of fixed air on iron and zinc. J. Priestley made some observations off the gas in 1767. Then followed, in 1774, T. Bergman's classical dissertation on the gas which he called *acris acidus*—the acid of the air. He showed that the gas behaves like acids in uniting

with bases like lime; that the gas is soluble in water, and the soln. like acids, reddens litmus, and that the gas is heavier than atm. air. He further proved that the presence of water is necessary for the union of the gas with quicklime, far, quoting an experiment by J. B. Bucquet (1773), "quicklime does not slake in fixed air but it may be instantly slaked in aerated water." J. B. M. Bucquet called the gas *acide à la craie*; J. Keir (1777), *calcareous gas*; and L. B. G. de Morveau (1782), *acide mephitique*, and the salts, *mephites*—e.g. mephite de potasse; mephite d'ammoniaque; etc. The term *gas mephitique* was elsewhere used for nitrogen, so that L. B. G. de Morveau's term was not adopted.

J. B. van Helmont assumed that the gas sylvestre in mineral water was derived from sulphur, and hence F. Hoffmann's term *spiritus sulphureus*; but G. E. Stahl (1702) did not accept this view. B. G. Sage regarded it as a kind of phlogisticated hydrochloric acid; and J. R. Deiman and P. van Troostwijk, P. J. Macquer, J. Priestley, C. W. Scheele, R. Kirwan, etc., made various suggestions in which fixed air was regarded as a combination of phlogiston with oxygen, nitrogen, or an acid. A. L. Lavoisier then showed that just as mercuric oxide is formed when mercury is heated in oxygen, so is fixed air formed when carbon is heated in that gas; and he re-christened fixed air, *acide carbonique* in harmony with the anti-phlogistian's views on combustion. A. L. Lavoisier, alone, and also in conjunction with P. S. de Laplace, showed that *acide carbonique* is a compound of 28.5 to 28.9 parts of carbon with 71.1 to 76.5 parts of oxygen. A. L. Lavoisier obtained the gas by the combustion of the diamond in oxygen, and S. Tennant analyzed it in 1797. Subsequent observations are indicated in connection with the at. wt. of carbon (*q.v.*). The gas now called *carbon dioxide* was liquefied by M. Faraday in 1823, and solidified by M. Thilorier in 1835.

§ 31. The Occurrence of Carbon Dioxide

Carbon dioxide is one of the most important of the accessory constituents of air. In 1796, H. B. de Saussure¹ directed special attention to the carbon dioxide content of the atm., and he established its presence in the mountain air of Switzerland as well as in the air of the plains. His son, N. T. de Saussure, followed up the inquiry in 1828-30, and concluded:

The quantity of carbon dioxide in the open air in the same place is subject to almost continual changes equally with the temp., the winds, the rain, and atm. press. . . . The augmentation of the average quantity of carbon dioxide in summer and its diminution in winter are manifested at different stations—in the country as in the city, upon the Lake of Geneva and upon a hill, and in calm and in disturbed air. . . . The ratio is not constant throughout the year. There are times which form exceptions, and in which the quantity of carbon dioxide in summer is inferior to that in winter, or *vice versa*. . . . The difference in the quantities of carbon dioxide contained in the atm. in calm weather, during day and night is one of the most remarkable results of my observations—more is present during the night than during the day. . . . The air of Geneva contains more carbon dioxide than the air of a meadow at Chambeiry.

At first, N. T. de Saussure believed that rain increased the proportion of carbon dioxide, but later found that a greater proportion was present in dry weather. A few analyses are quoted in Table XXI. Collections of data have been compiled by R. A. Smith, and by E. A. Letts and R. F. Blake. According to E. L. Moss, arctic air is richer in carbon dioxide than the air of England; A. Krogh found the proportion in Greenland to vary from 2.5 to 7.0 parts per 10,000; and R. Legendre found 3.5 parts in 10,000 in ocean air off Western France. In general, however, the proportion of carbon dioxide in the atm. is very nearly constant. Atm. air contains about 3 vols. of carbon dioxide per 10,000 vols. *i.e.* 0.046 per cent. by weight. These figures may be regarded as a norm or standard of reference. According to F. W. Clarke, this norm corresponds with about 2,200,000,000,000 tons of carbon dioxide, or 600,000,000,000 tons of carbon. A. Krogh estimated the total carbon dioxide in the atm. to be 2.4×10^{12} tons; and C. R. van Hise, and W. Dittmar obtained similar estimates, while T. C. Chamberlin made a rather higher estimate. There are moderate variations above and below the standard. In towns, for example, the proportion is greater, and in the open country it is less; but the excessive accumulation of this gas in any one locality is prevented by the circulation induced by winds and atm. currents, *vide* atmospheric air.

The chief sources of the carbon dioxide in the atm. are (i) the evolution of carbon dioxide from mineral springs, volcanoes, etc.; (ii) the combustion of fuels, thus, in 1844, J. B. J. D. Boussingault estimated that about 3,000,000 cub. metres of this gas were generated daily by the combustion of fuel, and by life in Paris, and A. Krogh estimated that about one-thousandth of its present content in carbon dioxide was added yearly to the atm. by the combustion of coal; (iii) the respiration of animals; (iv) the decay of organic matter; and (v), added F. W. Clarke, perhaps the majority of shooting stars represents the combustion of carbonaceous meteorites in the upper regions of the atm., and the consequent addition of carbon dioxide to the air. Few such meteors reach the earth. The main counterbalancing influences are (i) the decomposition of carbon dioxide by plants. H. T. Brown found that the air before passing through a vessel containing the leaves of a growing plant contained

INORGANIC AND THEORETICAL CHEMISTRY

2.80 parts of carbon dioxide per 10,000, and of leaving 1.77 parts per 10,000; the loss, 1.06, corresponded with an assimilation of 412 c.c. of carbon dioxide at n.t.p., per sq. metre of leaf surface per hour. Under constant illumination, the intake was directly proportional to the partial press. of the gas. E. H. Cook estimated that the leaf action alone more than compensates for the increase in the carbon dioxide in the atm., and without this influence, the amount of carbon dioxide in the atm. would double itself in a century. A part of the carbon dioxide withdrawn by plants is restored when the leaves decay in autumn, but a portion is withdrawn permanently. (ii) Carbon dioxide is consumed in the weathering of rocks. T. S. Hunt attempted to estimate the amount of carbon dioxide consumed in the production of china clay from orthoclase; and added that the carbon dioxide now represented by the carbonates of the earth's crust must have equalled two hundred times the entire amount in the present atm. The carbon of the coal measures and of the sedimentary rocks has all been directly or indirectly obtained from the atm. The soluble carbonates produced by weathering are washed into the ocean, and there transformed with sediments, shells, coral reefs, etc. The carbon of sedimentary rocks is estimated by F. W. Clarke to be about 30,000 times that contained in the atm., and T. C. Chamberlin estimated that 1,620,000,000 tons of carbon dioxide are annually withdrawn from the atm. in the formation of sedimentary rocks.

In 1848, J. Pelouze and E. Frémy pointed out that although no appreciable variation in the proportions of oxygen and nitrogen had been detected by analyses of atm. air, yet the methods of analysis are not exact, and that it is quite possible that the composition of the atm. is undergoing very slight variations which will become appreciable only after the lapse of a great number of years. J. B. A. Dumas, and J. von Liebig seem to have regarded the composition of the atm. as a fixed constant which is maintained by the mutual action of the animal and vegetable kingdoms whereby the former introduces carbon dioxide and the latter removes that gas and introduces oxygen. C. Martins, however, has shown that the supposed compensations must be fallacious when it is remembered that the quantity of oxygen consumed by the entire animal kingdom is out of all proportion to that contained in the entire globe—some 0.011 per cent. per century.

The comparatively large proportion of free oxygen in the atm. is remarkable when it is remembered what a strong affinity oxygen has for other substances—e.g. graphite, sulphur, pyrites, and other sulphides which occur in primitive rocks in an unoxidized state. These facts have been cited to support the thesis that *the primitive atmosphere of the earth contained no free oxygen*. It is agreed that the later deposits of coal and of the carbonate rocks were derived from the carbon dioxide formerly diffused in air and sea; and the great extent of coal deposits as contrasted with the more recent deposits of lignite and peat, has been cited to support the thesis that *a considerably larger proportion of carbon dioxide must have been present in the atmosphere during the period of the coal flora than now*. There is, however, nothing to show that this stored carbon was ever all present in the atm. at one time. It is further supposed that during this period, an evolution of oxygen from the vegetation must have occurred simultaneously with the absorption of oxygen. C. J. Koene, J. Lemberg, T. L. Phipson, Lord Kelvin, J. Stenenson, etc., argue that the earth's primitive atmi. contained very little oxygen, large quantities of carbon dioxide, and possibly appreciable quantities of hydrogen, carbon monoxide, and hydrocarbon gases. In further support of the argument, it is said that no oxygen is found in the gases extracted from rocks.

According to the nebular hypothesis, the temp. of the earth was once above the dissociation point of most oxides or oxygen compounds, and therefore the earth's supply of oxygen may have been free. On cooling, the oxygen united with the elements for which it had a sufficient affinity, first with the lighter and more oxidizable elements—silicon, carbon, aluminium, calcium, magnesium, potassium, and sodium—and a large quantity of silica or silicate would be formed as a thick

CARBON

surface later hindering the passage of the remaining oxygen to the still oxidizable elements lower down. Otherwise, the graphite and sulphides found in the oldest rocks would have been oxidized. It happens that there is about 6000 times more combined than free oxygen, so that the earth's supply has combined to the extent of 99.98 per cent. of the total, and it seems likely that all the oxygen would have been combined were it not for counteracting influences. Naturally, after the oxygen had been all consumed a considerable excess of hydrogen and hydrocarbon gases remained. This is evidenced by the spectra of the sun and stars, by the presence of metal carbides, and of occluded hydrogen in meteorites. It is then assumed that vegetation appeared, more or less anaerobic, and as the vegetation increased the proportion of oxygen in the atm. likewise increased, and the proportion of carbon dioxide diminished. As time went on, the amount of oxygen increased until animal life became possible and animals appeared. Animals take in oxygen and give off carbon dioxide. The two types of organism developed until a state of equilibrium was attained. According to this hypothesis nearly all the free oxygen at present in the atm. has been derived from carbon dioxide, and has been produced by the action of sunlight on vegetation growing in an atm. of this gas.

While the cooling earth was at a high temp. no carbonate could be present; they must have been formed after the earth had cooled. As indicated above, T. S. Hunt estimated that if all the carbon dioxide at present in the earth as carbonates were set free, the atm. would have 200 times its present amount. Such an atm. would have a much greater solvent action on silicate rocks, so that the rates of formation of carbonates and of the denudation of silicates would be greater than now. The effect of the weathering of silicate rocks is to decrease the amount of carbon dioxide and of water in air and sea. It is estimated that the water at present combined in terrestrial rocks amounts to about one-third or one-fourth of that contained in the ocean. W. Ostwald considers it probable that more carbon dioxide is withdrawn from the atm. than is restored; as a result, there is a slow diminution of the floating carbon-capital taking place on the surface of the earth. That change must be very slow, as is exemplified by the fact that analyses extending over a century show no definite alteration.

The premises from which this story has been elaborated are not unimpeachable. The observations which have been made at high temp. in electric furnaces have shown that the oxidized compounds were not necessarily formed first. The first compounds were probably carbides, silicides, etc., and in that case, all the oxygen would be atmospheric. As illustrating the extreme case, H. Lenicque argues that the great masses of limestone were formed by the atm. oxidation of the primitive carbides. In any case, it will be evident that two equally plausible lines of argument furnish opposing conclusions—one that the primitive atm. was rich in oxygen, and the other that it was free from oxygen.

There are other hypotheses. T. S. Hunt, and A. Winchell argued in favour of an atm. of carbon dioxide drawn from celestial sources; but there is no satisfactory evidence of this. S. Meunier combatted this hypothesis, and he favoured the assumption that the carbon dioxide was added to the primitive atm. by volcanic agencies. T. C. Chamberlin, and E. H. L. Schwarz favour the view that the planet was built up by accretion or the slow aggregation of small meteorites carrying occluded gases which formed the earth's atmosphere.

The carbon dioxide present in sea-water has been (i) absorbed from the atm. or brought down with the rain; (ii) carried in as hydrocarbonates by river-water; (iii) produced from decaying organic matter; (iv) produced by the respiration of aquatic animals; and (v) derived in part from submarine volcanic springs. The gas is liberated from the hydrocarbonates when coral and shell-building organisms assimilate the normal carbonate. Carbon dioxide is therefore continuously being added to sea-water, and it is continually being lost; it is either given up directly to the atm., or consumed in the maintenance of marine plants. T. Schlösing² has estimated that the ocean holds in soln. 18-27 times as much carbon dioxide as does the atm., and he regarded

the ocean as the great regulative reservoir of this gas. There is a continuous interchange of carbon dioxide between the ocean and the atm.; the gas is released from the waters in warm climates, and absorbed in cold regions. Hence the atm. supply is alternately being enriched and impoverished. The regulating action of water in maintaining the state of equilibrium necessary for the welfare of animals and plants was first pointed out by E. Lélige in his *Études sur la composition des eaux*, in 1855. The rain-water absorbs some gas from the atm., and still more on coming in contact with the soil; then carbonates are dissolved as hydrocarbonates, which eventually make their way to the ocean. C. F. Tolman has discussed the conditions of equilibrium. Analyses of the gases in sea-water have been made by O. Jacobsen, H. Tornöe, K. Natterer, etc. Usually, there is not sufficient to transform all the calcium carbonate into the hydrocarbonate. J. Y. Buchanan, and W. Dittmar found the amount of carbon dioxide in sea-water in excess of that required for the formation of normal calcium carbonate in mgrms. per litre to be, at different temp.

	25°-28°	20°-25°	15°-20°	10°-15°	5°-10°	-1°-3°
CO ₂	35.88	37.18	42.68	43.50	47.21	53.31

Hence, the ocean contains less carbon dioxide in warm than in cold latitudes—the average may be taken as 45 mgrms. per litre. The variations at different depths are less marked:

	Surface	100 fath.	400 fath.	800 fath.	Over 800 fath.	Bottom
CO ₂	42.6	43.6	41.1	42.2	44.6	47.4

G. Linck found the maximum solubility of calcium carbonate in sea-water to be 0.191 grm. per litre at 17°-18°; and W. Dittmar found the average sea-water to contain 0.121 grm. per litre. J. Johnston and E. D. Williamson considered the warm surface layers of the ocean to be practically sat. with carbonates which are subject to precipitation by changes of temp., and by fluctuations in the proportion of carbon dioxide in the atm. above. J. Y. Buchanan found that the carbon dioxide was sometimes in excess of that necessary to form hydrocarbonates, and sometimes just sufficient to convert the normal carbonates into the acid salt.

Carbon dioxide is found free or combined in mineral and spring waters³—e.g., Carlsbad, Seltzer, etc. The original *Apollinaris* is a natural water from a spring in the Valley of Aar, near the Rhine, which has carbon dioxide in soln., and an acid reaction, while the waters of Vichy, Neuenahr, etc., have an alkaline reaction, although the same gas is in soln. Apollinaris and other natural waters are bottled and exported, and they are imitated artificially and sold as "mineral waters." The acidity of water containing carbonic acid plays a great part in geological changes—*vide* the weathering of silicates.

Carbon dioxide issues as a gas from many parts of the earth. C. St. C. Deville and F. le Blanc's analysis⁴ of the air in the Grotta del Cane gave 70.35 per cent. CO₂, 23.7 per cent. N₂, and 6.0 per cent. O₂. A stratum of *spiritus lehalis* is said to occupy the lower portion of the cave to a depth of about 18 inches on the floor, so that dogs, whose nostrils are near the ground, are suffocated, while men are safe. During the 1869 eruption of Vesuvius, F. Gorceix said the gas which escaped was virtually pure carbon dioxide. Pliny said that some persons call vents emitting nephritic fumes, *Charoneas scrobes*—Charon's sewers. The Poison Valley or the Valley of Death in Java is an old volcanic crater with fissures from which are evolved large quantities of carbon dioxide which fill the valley as water fills a lake. The flow is apparently intermittent because sometimes scarce a trace of gas can be found, at other times it fills the valley. A. Loudon thus describes his observations:

We took with us two dogs and some fowls to try experiments in this poisonous hollow. On arriving at the foot of the mountain we dismounted and scrambled up the side about a quarter of a mile, holding on by the branches of trees. When within a few yards of the valley we experienced a strong nauseous suffocating smell, but on coming close to its edge

this disagreeable odour left us. The valley appeared to be about half a mile in circumference, oval, and the depth from thirty to thirty-five feet, the bottom quite flat; no vegetation; strewn with some very large (apparently) river stones; and the whole covered with the skeletons of human beings, tigers, pigs, deer, peacocks, and all sorts of birds. We could not perceive any vapour or any opening in the ground, which last appeared to us to be of a hard sandy substance. It was now proposed by one of the party to enter the valley; but at the spot where we were this was difficult at least for me, as one false step would have brought us to eternity, seeing no assistance could be given. We lighted our cigars, and, with the assistance of a bamboo, we went down within eighteen feet of the bottom. Here we did not experience any difficulty in breathing, but an offensive nauseous smell annoyed us. We now fastened a dog to the end of a bamboo eighteen feet long, and sent him in: we had our watches in our hands, and in fourteen seconds he fell on his back, did not move his limbs or look round, but continued to breathe eighteen minutes. We then sent in another, or rather he got loose, and walked in to where the other dog was lying. He then stood quite still, and in ten minutes fell on his face, and never afterwards moved his limbs: he continued to breathe seven minutes. We now tried a fowl, which died in a minute and a half. We threw in another, which died before touching the ground. During these experiments we experienced a heavy shower of rain; but we were so interested by the awful sight before us that we did not care for getting wet. On the opposite side, near a large stone, was the skeleton of a human being, who must have perished on his back, with his right hand under his head. From being exposed to the weather the bones were bleached as white as ivory. I was anxious to procure this skeleton, but any attempt to get it would have been madness.

The Death Gulch of the Yellowstone Park, Cal., is another such valley, where it is said that grizzly bears are sometimes found suffocated to death by the carbon dioxide which issues from the ground. The Laacher Sea is the water-filled crater of a prehistoric volcano, and near by is a depression filled with this gas. Birds and insects flying in this region are suffocated. The gas, issuing from outlets in the vicinity, tends to collect in the cellars of houses, where it has caused many tragedies by suffocating those who incautiously enter. The gas is also emitted from numerous fumeroles and rents in the ground in the old lavas at Brohl in the Eifel; in the caves at Pyrmont; at Lahntal near Buns; Taunus; near Driburg in Westphalia, Sondershausen in Thuringia, Montpensier, etc. In Auvergne in the neighbourhood of Vichy and Hauterive, the gas has been utilized in the manufacture of white-lead. The presence of carbon dioxide has been recorded in volcanic gases.⁵ After an eruption at Vesuvius, the carbon dioxide has been reported to come from the ground, in the vicinity (*vide supra*), in such quantities as to asphyxiate numerous small animals and to fill the cellars of the houses. Torrents of the gas are evolved from the craters in South America. J. B. J. D. Boussingault estimated that Cotopaxi emitted more carbon dioxide annually than was produced by combustion and respiration in the city of Paris. The 1783 eruption at Skaptar Jokull, Iceland, is said to have suffocated thousands of men and hundreds of thousands of cattle. Carbon dioxide has been reported in the gases from the salt deposits at Stassfurt,⁶ and in the gases from coal,⁷ and soils.⁸ Processes of oxidation in the soil impoverish the oxygen in the air of wells, and mines, and form carbon dioxide. It has been estimated that an acre of good garden land in summer evolves more than six tons of carbon dioxide derived from the oxidation of the organic matter in the soil. Again, the oxidation of iron pyrites furnishes sulphuric acid which coming in contact with the carbonates yields carbon dioxide. The so-called *choke-damp*, or *black-damp*, contains 85 to 95 per cent. of nitrogen and 5 to 15 per cent. of carbon dioxide. According to C. le Neve Foster and J. S. Haldane, an enormous quantity of black-damp is formed in mines: 2000-5000 c. ft. per minute is a common quantity; and the oxidation process which produces it is the chief source of heat in mines. Choke-damp issues from soils into mines or wells when the barometric column is falling. Meteorites⁹ may contain carbonates; and carbon dioxide has been reported to occur in blood,¹⁰ urine,¹¹ muscles,¹² etc. Carbon dioxide occurs as an inclusion in cavities in many minerals.¹³ Numerous metal carbonates occur in nature; they are discussed in connection with the respective metals.

§ 32. The Metabolism of Animals and Plants

Two chemical individuals stand alone in importance for the great biological cycle upon earth. The one is water, the other carbon dioxide. . . . These two simple substances are the common source of every one of the complicated substances which are produced by living beings, and they are the common end products of the wearing away of all the constituents of protoplasm, and of the destruction of those materials which yield energy to the body.—E. J. HENDERSON (1913).

In 1674, John Mayow¹ demonstrated that the respiration of animals is a process of oxidation analogous with combustion. J. Mayow placed a mouse in a cage under a vessel standing over water—Fig. 42—and noticed that the water rose in the jar as respiration continued just as if a burning candle had been placed under the jar, owing to the withdrawal of "nitroaërial particles" (oxygen). He found that the mouse died after a time, and it was impossible to ignite a combustible body in the residual "aërial" gas (nitrogen).

Metabolism of animals.—Organisms are continually wasting tissue as a result of muscular or other forms of work. Those constructive processes by which sub-

stances taken in as food by living organisms are converted into protoplasm are said to be **anabolic**—from *ἀνά*, *anw*; *βάλλειν*, to throw. Those destructive processes by which the protoplasm, etc., breaks down into simpler products are termed **katabolic**—from *κατά*, down. The two phenomena are included under the term **metabolism**—*μετά*, about. The air during respiration loses about 4 to 5 per cent. of oxygen, and gains 3 to 4 per cent. of carbon dioxide. Oxygen, taken in by the lungs, is absorbed by the blood. The blood contains **hæmoglobin**; this unites with oxygen, forming **oxyhæmoglobin**—the former is present in blue venous blood; the latter is red arterial blood. The oxyhæmoglobin gives up its oxygen very readily, and it thus oxidizes the waste products—partly to carbon dioxide. The carbon dioxide held in soln. by the venous blood is pumped by the heart to the lungs, and the gas is finally exhaled in the breath.

By breathing into a beaker, and then adding clear lime-water; or better, by blowing through a glass tube into a beaker containing clear lime-water, it is easy to demonstrate the presence of carbon dioxide in the breath. The precipitation of calcium carbonate causes the clear lime-water to become turbid, etc. The experiment can be modified by drawing a stream of air through pieces of soda-lime in a tower, *A*, Fig. 43, to remove carbon dioxide

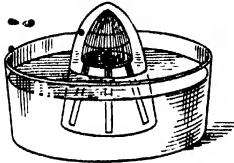

FIG. 42.—J. Mayow's Experiment on Respiration.

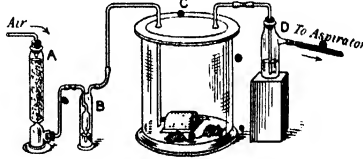

FIG. 43.—Exhalation of Carbon Dioxide by Animals

from the air: then through a wash-bottle, *B*, with clear lime-water. The clarity of the lime-water demonstrates the absence of carbon dioxide in the stream of air. The air after passing the *temon* (witness) tube, *B*, enters a glass chamber, *C*, which holds a mouse or a couple of mice, and then passes through another wash-bottle, *D*, containing clear lime-water. The turbidity of the lime-water in *D*, and the clarity of the lime-water in *B*, can be explained only by assuming that the mice are giving off carbon dioxide during respiration.

Less carbon dioxide is exhaled during sleep because less waste products are formed. The heat evolved during the oxidation processes in the body maintains the body at the necessary temp. In the case of plants, most of this work is done by the leaves. The respiration of animals and plants goes on continuously, night and day—oxygen (air) is taken in, and returned to the air as carbon dioxide and water. The consequent loss in weight in both animals and plants is made good by assimilation or feeding. Fish abstract dissolved oxygen from water by means of their gills. Fish quickly die for want of oxygen when placed in cold water which has been deprived of dissolved air by boiling. Aerated water furnishes the oxygen necessary for their sustenance.

Assimilation by plants.—The respiration of plants must not be confused with the process of assimilation. In daylight, green plants absorb carbon dioxide from the air, fix the carbon, and give off oxygen. In sunlight, the process is very active, so that the respiration process, though at work, is masked because more carbon dioxide is taken in and oxygen given out by assimilation (feeding) than oxygen is taken in and carbon dioxide given out by respiration (breathing). The decomposition of the carbon dioxide (feeding) occurs only in daylight, and plant life is thus dependent upon this process for nourishment.

This action of light may be readily shown by modifying an old experiment due to J. Ingenhouz. A two-litre flask is loosely packed with green leaves, and filled up with water through which carbon dioxide has been allowed to bubble. Fit the flask with a stopper, and

funnel as shown in the diagram, Fig. 44. Also fill the flask and part of the funnel with water. A test-tube inverted over the funnel will collect sufficient oxygen to allow the usual tests being made. Carbon dioxide can be removed from the gas by a soln. of potassium hydroxide.

In 1774, J. Priestley observed that air spoiled by mice so that it is rendered incapable of supporting animal life, can be made good by allowing green plants to remain in it for some time. Six years later, J. Ingenhousz found that this action occurs only in light. He said that

The light of the sun is alone capable of producing in the leaves that movement which can develop dephlogisticated air (oxygen) . . . as soon as the light ceases to act on the leaves, the operation ceases at the same time, and another of a different nature commences.

Fig. 44.—As a simulation of Carbon Dioxide by Plants.

In 1783, J. Senebier showed that the chemical changes which occur result in transforming fixed air (carbon dioxide) into dephlogisticated air (oxygen). N. T. de Saussure, in 1804, also investigated the phenomenon. Only the green parts of plants are able to decompose atm. carbon dioxide in the presence of sunlight. In plants, the green pigment, **chlorophyll**, is associated with living protoplasm, forming granular masses called **chloroplasts**—studied by C. Timiriazoff. The nature of the green pigment has been discussed by R. Willstätter and A. Stoll. The absorption spectrum of chlorophyll has bands in the red and blue, practically none in the ultra-red or in the yellowish-green, but there is a faint one in the ultra-violet. The most striking feature is the dark band in practically the position of the maximum energy of the solar spectrum. T. W. Engelmann, H. Kniep and F. Minder, and C. Timiriazoff have demonstrated that the maximum evolution of oxygen occurs where there is the greatest absorption of light.

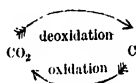

Radiant energy is stored up by the insolated chlorophyll. The decomposition of the carbon dioxide at ordinary temp. requires the expenditure of energy. The process is not catalytic. F. Weigert explains this by assuming that the chlorophyll itself takes part in the reaction, and that the increase in potential is due to the physiological processes in the protoplasm of the chloroplasts.

According to M. Trautz, the process is accompanied by chemi-luminescence so that the reddish light emitted has the same wave-length as the main absorption band of the chlorophyll. Starting then from the energy stored by the chlorophyll and carbon dioxide, A. von Baeyer suggested that formaldehyde, H.CO.H , is the first product of the reaction: $\text{CO}_2 + \text{H}_2\text{O} = \text{H.CO.H} + \text{O}_2$, and that the end-product of the photosynthesis is a polymer of formaldehyde: $6(\text{H.CO.H}) = \text{C}_6\text{H}_{12}\text{O}_6$. He assumed that the carbon dioxide breaks down: $\text{CO}_2 = \text{CO} + \text{O}$, and the product reacts: $\text{CO} + \text{H}_2\text{O} + \text{O} = \text{O}_2 + \text{H.CO.H}$; E. Erlenmeyer, however, assumes that formic acid, H.CO.OH , and hydrogen dioxide are first produced: $\text{CO}_2 + 2\text{H}_2\text{O} = \text{H.CO.OH} + \text{H}_2\text{O}_2$, and that these products interact, giving formaldehyde: $\text{H.CO.OH} + \text{H}_2\text{O}_2 = \text{H.CO.H} + \text{H}_2\text{O} + \text{O}_2$. A. Bach, indeed, obtained formic acid by the action of light on carbon dioxide in the presence of a soln. of a uranium salt, and assumed that the first stage of the reaction involves the formation of precarbonic acid and formaldehyde: $3\text{CO}_2 + 3\text{H}_2\text{O} = 2\text{H}_2\text{CO}_4 + \text{H.CO.H}$, followed by $\text{H}_2\text{CO}_4 = \text{CO}_2 + \text{H}_2\text{O}_2$. F. L. Usher and J. H. Priestley have studied the mechanism of the carbon assimilation; they found an aldehyde and hydrogen dioxide among the products of the action of light on films of chlorophyll in the presence of moist carbon dioxide. The work of S. B. Schryver, H. Wager, and C. H. Warner makes it doubtful if an aldehyde can be produced from carbon dioxide and water by chlorophyll alone without the intervention of protoplasm. The production of formaldehyde from carbon dioxide has been studied by F. Hoppe-Seyler, F. L. Usher and J. H. Priestley, T. Curtius and H. Franzen, F. Weigert, B. Moore, S. M. Baker, R. Willstätter and A. Stoll, O. Warburg and E. Negelein, etc.—vide chemical properties of carbon dioxide.

The energy required for the decomposition of the carbon dioxide is derived mainly from the radiant energy of the sun. There is thus a transformation of the sun's radiant energy into chemical energy which is stored up as vegetable tissue. The heat of combustion of burning food is believed to be eq. to the solar energy used in its formation (Hess' law). At night, i.e. in darkness, feeding stops, but breathing—the absorption of oxygen and the evolution of carbon dioxide—continues. The net result of both processes—assimilation and respiration—is to remove carbon dioxide from the air, and restore oxygen. There is probably a kind of equilibrium press. between plants and the carbon dioxide of the air. If the amount of carbon dioxide exceeds a certain limit, this would be followed by greater activity in vegetable life, and thus the normal proportion of carbon dioxide would be restored. Similarly, if the amount of carbon dioxide were reduced below the normal, vegetable life would be impoverished until equilibrium was restored. The proportion of carbon dioxide present in the gases dissolved by sea-water is about 27 times as great as the proportion of this gas in air. Since carbon dioxide is fairly soluble in water, it follows that if a large surplus of carbon dioxide were introduced into the atm., say, from volcanic sources, the sea would dissolve a still greater proportion. Hence, as indicated above, the sea must be an important means of regulating the amount of carbon dioxide in the atm.

It will be noticed that all animal and vegetable life is dependent upon the carbon dioxide \rightarrow carbon reaction, which in turn is dependent upon the sun's energy. There is a kind of closed cycle, an alternation of oxidations and deoxidations:

Sun's energy stored Plants feed

Energy dissipated—animals and plants breathe, etc.

maintained by a continuous supply of energy from the sun. If the supply should cease, the deoxidation of carbon dioxide would stop and the present conditions of life on the earth would come to an end. Because the available carbon would be transformed into unavailable carbon dioxide.

33. The Formation and Preparation of Carbon Dioxide

In some districts carbon dioxide is collected from springs—e.g. the natural waters from the Saratoga Springs (New York), and in South Germany. Borings are made, and a basin is excavated about each bore-hole. The basin is filled with water from the bore-hole, and the excess is allowed to escape by an overflow channel. A kind of gasometer is placed over the bore-hole so as to collect the gas. The gas is led from the gas-holder, and purified by passing through a spraying apparatus. A little potassium permanganate may be added to oxidize such impurities as hydrogen sulphide.¹

Carbon dioxide is the end-product of the combustion of carbon in its various forms—vide carbon. In technical work, when contamination with nitrogen is of no moment, carbon dioxide is obtained by passing air over heated carbon—charcoal, coke, etc. Furnace gases resulting from the combustion of coke, charcoal, etc., may have up to 20 per cent. by vol. of carbon dioxide. The carbon dioxide so formed can be isolated by passing the gas into a soln. of potassium or sodium carbonate, so as to form the hydrocarbonate: $K_2CO_3 + H_2O + CO_2 = 2KHCO_3$; the gas can be recovered by heating the hydrocarbonate. Many modifications of this process have been suggested.² The exhaust gas from gas-engines has also been employed. The sulphur dioxide and dust are removed by passing the gas through scrubbers containing limestone over which water trickles. L. Hackspill and A. Couder noted the formation of nitrates and nitrites in the preparation of carbon dioxide by the combustion of coke. The formation of carbon dioxide in the combustion of carbon monoxide has been treated in connection with the latter gas. The preparation of carbon dioxide from water-gas has been treated by C. Arnais,³ and J. Pullman and H. S. Elworthy.

The slow oxidation of hydrocarbons, said F. C. Phillips,⁴ always yields carbon dioxide; ethylene is oxidized by a soln. of potassium permanganate in sulphuric acid below 100°; and acetylene is oxidized by the same soln. cold, as well as by calcium hypobromite, or by osmic acid. O. Angelucci found that when acetylene is heated with oxygen and nitrogen in the presence of platinum sponge: $2C_2H_2 + 5O_2 (+5N_2) = 4CO_2 + 2H_2O (+5N_2)$, or $C_2H_2 + 2O_2 (+2N_2) = CO_2 + CO + H_2O (+2N_2)$. J. Coquillion and L. Henrivaux passed ethylene and water vap. through a red-hot porcelain tube packed with bits of porcelain, or pumice-stone, and, at a bright red heat, the product contained 15.7 per cent. of carbon dioxide and 24.7 per cent. of ethylene; at a higher temp. a larger proportion of ethylene and carbon dioxide was formed. The fractional oxidation of the hydrocarbons has been discussed in connection with carbon monoxide. R. Pippig and O. Trachmann discussed the purification of coal gas, and the subsequent formation of carbon dioxide from the products of combustion. C. G. P. de Laval obtained carbon dioxide from the products of combustion of petroleum. Carbon dioxide is produced by the action of steam on heated carbon (*q.v.*). E. E. Arnold obtained it by the action of air on molten pig iron.

The carbon in organic substances furnishes carbon dioxide during oxidation partly by air and partly by the contained oxygen, at ordinary temp. or when warm. The gas, for example, is produced during fermentation.⁵ Enormous quantities are evolved as a by-product during the manufacture of beers, wines, etc., in the alcoholic fermentations of sugar: $C_6H_{12}O_6 = 2C_2H_5OH + 2CO_2$. The gas so produced has a flavour like that of fusel oil, but it can be used for some purposes as discussed by H. Kerr-Thomas, J. C. Stead and T. C. Palmer, R. Thalwitzer, J. L. Seyboth, C. Dörries, etc. None of the proposed methods has been successful from an industrial point of view. F. Stolba obtained a very slow current of carbon dioxide from a mixture of 5 vols. of yeast with 1000 vols. of a soln. of one part of sugar in four parts of water. Carbon dioxide is formed during the putrefaction and decay of organic matter.⁶ It is formed during respiration,⁷ during muscular work,⁸ and during the germination of plants.⁹

H. Karsten¹⁰ found that various organic substances furnish carbon dioxide

when exposed to ozonized air. Carbon, and various organic substances evolve carbon dioxide in contact with oxygenated compounds at ordinary or at elevated temp., thus, A. F. Pol, and E. Moride observed that many soln. of the metal salts are reduced by carbon with the formation of carbon dioxide. Several other reactions have been indicated in connection with the chemical activity of carbon, carbon monoxide, oxychloride, oxysulphide, and disulphide. P. Schützenberger¹¹ found that when carbon tetrachloride is heated many hours with zinc oxide, at 200°, carbon dioxide is formed. H. St. C. Deville and H. Debray found that powdered rhodium converts formic acid into carbon dioxide. A. Richardson found an aq. soln. of oxalic acid in light furnishes carbon dioxide and water, and may be hydrogen dioxide. According to C. Wilde, fuming sulphuric acid and citraconic anhydride give carbon dioxide at 150°-160°, and carbon monoxide at 220°. A. Bouvier patented a process for the preparation of a mixture of carbon dioxide and acetylene by the action of water on a fused mixture of powdered calcium carbonate and carbide, and sodium hydrosulphate, NaHSO_4 .

Carbon dioxide is obtained by heating various carbonates to suitable temp.—e.g. dolomite, lime-stone, magnesite, sodium hydrocarbonate, barium carbonate, manganese carbonate, etc. The gas is a by-product in the burning of limestone and marble for lime, or magnesite for making magnesia bricks. The evolved gas contains about 30 per cent. of carbon dioxide; the remainder is nitrogen and carbon monoxide. Some of the carbon dioxide is derived from the fuel. Many processes have been devised for collecting and purifying the gases from lime-kilns or magnesite-kilns—*vide supra* on the recovery of carbon dioxide from flue gases.¹² The gas can be purified from nitrogen, etc., by passing it into a soln. of alkali carbonate as indicated above. G. Bischof¹³ decomposed magnesium carbonate by steam; and V. A. Jacquelin showed that the carbonates of sodium, silver, calcium, barium, magnesium, and lead are decomposed, when heated in steam. M. Meschelyneck and J. F. Lionnet found calcium carbonate is decomposed by steam at a dull red heat. The manufacture of carbon dioxide by the action of steam on limestone has been treated by J. Daughish, H. Blair, G. M. Westmann, E. Luhmann and G. A. Schütz, etc. The decomposition of the sodium hydrocarbonate by steam has been investigated by J. Young, and A. Campbell and co-workers. L. A. Staub¹⁴ discussed the decomposition of sodium hydrocarbonate by ammonia; H. Howard, its decomposition by sodium hydrosulphate; H. Grimshaw, and E. Sandow, its decomposition by sodium hydrosulphate; M. G. Elledge, by calcium chloride; H. and J. F. Beins, its decomposition by ammonia-alum, or potash-alum; C. Löwig, the decomposition of carbonates by heating them with ferric oxide; and J. L. W. Thudichum and J. A. Wanklyn, by potassium dichromate.

Carbon dioxide is usually prepared in the laboratory by the action of different acids on various carbonates. For example, magnesite, limestone, and marble may be decomposed with dil. nitric acid as recommended by J. G. Bogusky,¹⁵ J. G. Bogusky and N. Kajander, and I. Langmuir; with dil. hydrochloric acid, or hydrobromic acid as recommended by N. N. Beketoff. Sodium carbonate or hydrocarbonate may be decomposed with sulphuric, or hydrochloric acid, with tartaric acid as recommended by W. B. Dick; or with sodium hydrosulphate as recommended by H. Bornträger, E. Grimshaw, and E. Sandow. J. A. Ageron and B. J. M. Remy heated a mixture of magnesium sulphate and sodium sulphate or hydrosulphate with sulphuric acid, and used the product as a substitute for acids in liberating carbon dioxide from carbonates. F. Menter and W. A. Sedlitzky added to water a mixture of a carbonate or hydrocarbonate with a readily hydrolysable salt—e.g. alum, aluminium sulphate, or ferrous sulphate. J. H. Niemann decomposed ammonium carbonate with dil. sulphuric acid. R. C. Farmer described an apparatus for preparing carbon dioxide free from measurable quantities of air from a soln. of potassium hydrocarbonate (300 grms. per litre) and dil. sulphuric acid (1:8). L. Moser discussed the purification of the gas, using a paste of chromous acetate, and a 15 per cent. soln. of titanous chloride in hydrochloric acid to remove oxygen; heated cuprous oxide to remove

carbon monoxide; cupric sulphate on pumice to remove hydrogen sulphide; and a soln. of potassium permanganate to remove sulphur dioxide.

The acid process is used industrially, but not nearly so much now as formerly. The carbonate in the generator is mixed with water. The generator is cylindrical and constructed of lead, or of cast iron lined with lead. A safety-valve and an agitator are provided. The conc. acid is run from an acid-tank into the generator usually in quantities not sufficient to neutralize the carbonate. Sulphuric acid is preferred to hydrochloric acid because the volatile impurities in the gas from the last-named acid render the purification of the final product more costly. The sulphuric acid should be free from appreciable amounts of arsenic if the gas is to be used for mineral waters. If sulphuric acid were to be used with marble or whiting, a troublesome mass of sparingly soluble calcium sulphate would be left in the generator. Sodium hydrocarbonate with sulphuric acid is expensive; marble frequently contains bituminous impurities which contaminate the gas with substances difficult to remove. Whiting requires to be mixed with more water than does marble before the addition of the acid. This makes a proportionally larger generator necessary. Magnesite can be used with sulphuric acid: it gives a high yield of gas (52 per cent. by weight), and the mother-liquid can be worked for magnesium sulphate.

The gas usually needs purification. A certain amount of purification is effected on a large scale by passing the gas through water-scrubbers. If the gas still possesses an unpleasant odour, it is purified by passing it through a soln. of potassium permanganate which destroys the organic compounds and hydrogen sulphide; and through a soln. of sodium hydrocarbonate, which retains acid fumes. Sometimes manganese dioxide or potassium permanganate is added directly to the generator when sulphuric acid, but not hydrochloric acid, is used. J. Stenhouse,¹⁶ and J. Förster recommended purifying the gas from objectionable odours by passing it over pieces of wood charcoal. To remove hydrogen sulphide, when working on a small scale, H. Hager passed the gas through an acid soln. of ferric sulphate, then through a dil. soln. of iodine, then through two wash-bottles containing an aq. soln. of potassium permanganate, and finally through water. N. Gräber said that potassium permanganate, or other oxidizing agents does not always remove the objectionable odour from the gas. E. Pfeiffer recommended scrubbing the gas with olive oil to get rid of the odour. H. Reinsch said that it is simplest to destroy the bituminous matters by pre-heating the limestone or dolomite to a low temp. The impurities in liquefied carbon dioxide were discussed by O. Wentzky, H. Lange, J. C. A. S. Thomas, R. Woy, H. Thiele and H. Deckert, and J. Werdter. V. Cremieu and A. Lepape purified the gas by the solidification of the carbon dioxide, and pumping off the less condensable gases; and A. A. Backhaus, by passing it over activated carbon.

I. Langmuir recommended preparing carbon dioxide from marble and purified 50 per cent. nitric acid. The marble was boiled several times with weakly acidulated water to free it from air, and the acid was freed from air by a stream of carbon dioxide. The gas was purified by passing it through a sat. soln. of sodium hydrocarbonate, then through conc. sulphuric acid, and finally dried by passing the gas through a long tube containing phosphorus pentoxide. Numerous varieties of apparatus¹⁷ have been devised for the intermittent supply of carbon dioxide by the action of acid on a carbonate. Many of these are also used for hydrogen sulphide, etc. F. Küspert obtained small quantities of the gas from a syphon of soda water.

On an industrial scale carbon dioxide may be obtained from lime-kilns;¹⁸ from producer gas, combustion gases;¹⁹ from fermentation processes and other processes²⁰ in which the gases are absorbed by a soln. of sodium carbonate, and the soln. of hydrocarbonate heated to drive off the absorbed gas. L. Hækspill and A. Couder found nitric acid in the gas derived from potassium hydrocarbonate. This salt was made from carbon dioxide obtained from coke, and the nitric acid was derived from the nitrous acid formed during the oxidation of the nitrogen compounds when the coke was converted into carbon dioxide.

§ 34. The Physical Properties of Carbon Dioxide . .

Carbon dioxide is an invisible, colourless, and odourless gas at ordinary temp. A. L. Lavoisier's¹ statement that the gas has a feeble odour shows that his product was probably impure, but when breathed through the nostrils it does give a tingling sensation, due, probably, to its forming carbonic acid with the moisture; this also accounts for its having an acid taste. Liquid carbon dioxide was found by M. Faraday, J. H. Niemann, L. P. Cailletet, and B. Schwalbe to be a water-clear, colourless, very mobile liquid. M. Thilorier stated that the solid is a white flocculent mass resembling snow, and, like snow, is readily compressed. H. Landolt obtained dense hard cylinders of the compound by compressing the snow. M. Faraday, and A. Loir and

C. Drion obtained the solid as a colourless mass resembling ice, which, when fractured furnished small cubes. The ice-like form is obtained by cooling the liquid *en masse*; or, according to U. Behn, by cooling the vap. in a chamber below -70° . A. Liversidge said that the crystals resemble those of gold, iron, or ammonium chloride, and belong to the cubic system, although they volatilized before measurements could be made. P. Villard and R. Jarry said that the crystals do not act on polarized light. A. Liversidge, and H. E. Behnken found that the clear optically isotropic crystals belonged to the cubic system, and showed both cubes and octahedra. The sharpest and best formed crystals were liable to explosive rupture owing to contraction strains. According to W. Wahl, when carbon dioxide is cooled by liquid air, it condenses in the form of small cubes which are quite isotropic. No polymorphic change was observed above -210° . H. Mark and E. Pohland obtained **X-ray-crystals** in agreement with an elementary cube of side 5.62\AA . M. Thilorier said: When the solid is exposed to air it disappears insensibly by slow evaporation, without melting. A fragment of the solid, slightly touched by the finger, glides rapidly over a polished surface, as if it were sustained by the gaseous atm. with which it is constantly surrounded. The vaporization of solid carbon dioxide is complete; it leaves but rarely a slight humidity which may be attributed to the action of air on a cold body, the temp. of which is far below that of freezing mercury. The snow can be handled without harm, but when pressed on the skin, for a few seconds or more, it produces blisters.

The gas is about one and a half times as heavy as air, and this explains its tendency to accumulate in low-lying places—valleys, cellars, etc.—*vide* the occurrence of this gas.

The invisibility of the gas, its heaviness compared with air, and its property of quenching flame, enable many pleasing and attractive experiments to be arranged; their variety is limited only by the ingenuity and skill of the experimenter. Thus: (1) a long cardboard gutter leading into a glass trough in which a number of candles are burning can be arranged. The invisible gas, carbon dioxide, can then be poured from a large beaker down the gutter, when the candles will be extinguished just as if water had been poured down the gutter. (2) A cylinder can be arranged with candles at different levels; the gas when led into the cylinder, extinguishes the candles one by one as the gas rises in the jar. (3) A wheel of stiff cardboard can be mounted upon two corks on a knitting needle journaled into a wooden standard; paper buckets can be attached to the periphery of the disc by joining the edges of the paper so as to form a hollow cone. When carbon dioxide is poured into the buckets, the wheel will rotate, if properly balanced, as it were a "water wheel," moved by a stream of water. (4) A cardboard box, or a light glass vessel, can be counterpoised on a balance; the beam will be depressed when carbon dioxide is poured into the box, showing that the carbon dioxide is heavier than the air displaced. (5) Soap-bubbles blown with the air can be floated on the carbon dioxide in a large dish. (6) Petroleum burning in a shallow dish can be extinguished by pouring the gas over the dish; and a beaker of the gas poured over a lighted candle will quench the flame. (7) Carbon dioxide can be ladled from a large cylinder by a small tapper tied on to a string. The action is analogous with the method of emptying a well of water by means of a bucket and rope. Finally, a candle will burn in the cylinder, showing that the carbon dioxide has been removed. The beakers of carbon dioxide can be emptied into another cylinder and the presence of carbon dioxide demonstrated in the usual way.

F. Mohr² gave 22 for relative density, at n.p.t., if $H=1$; and J. P. Cooke, 21.971. R. F. Matchand gave 1.3819 to 1.3825 if $O=1$; and P. A. Guye, 1.3833. L. Bleckrode gave 1.529 (air unity) at 15° and 760 mm. With air at n.p.t. unity, R. F. Matchand gave 1.5282; H. V. Regnault, 1.51910; F. J. Wrede, 1.52037; J. J. Berzelius and P. L. Dulong, 1.5245; F. Exner, 1.52; E. Wiedemann, and R. K. McClung, 1.529; J. M. Crafts, 1.52897; J. P. Cooke, 1.52856; A. Leduc, 1.5287; Lord Rayleigh, 1.52909; R. J. Strutt, 1.53; and N. S. Drenteln, 1.50 to 1.52. According to J. P. Cooke, the calculated density is usually smaller than the observed value because the gas under atm. press. is more strongly compressed and much nearer its point of liquefaction, than the standard of comparison. F. Emich found 1.485 at 1000° , 1.497 at 1500° , and 1.527 at 2000° ; and with gas dried by sulphuric acid, 1.557 at 19° and 1.550 at 1875° —all referred to nitrogen unity. A. P. Lidoff said that the density of carbon dioxide from various natural sources

is lower than the theoretical. E. Mathias studied the density curve at low temp. and near the critical point.

L. P. Cailletet and E. Mathias, E. H. Amagat, P. Phillips, and U. Behn measured the vap. density of carbon dioxide at different temp.—*vide infra*. According to H. V. Regnault, the weight of a litre of the gas at 0° and 760° is 1.97774 grms. under standard conditions; E. Dietrich, 1.9678; J. M. Crafts gave 1.97772; P. A. Guye, and P. A. Guye and A. Printz, 1.9768; A. Leduc, 1.9763; Lord Rayleigh, 1.9769; and A. Jaquerod and F. L. Perrot, 1.97677, and at 1067.4° and 760 mm., 0.39986 gm. S. W. Parr has calculated a table of values between 10° and 30°, 720 to 770 mm. press., and latitude 41°, and altitude 100 metres.

The specific gravity of liquid carbon dioxide was given by M. Thilorier³ as 0.38 at 0°; 0.90 at -20°; and 0.60 at 30°; E. Andréeff gave 0.9470 at 0°; T. Bleekrode, 0.863 at 15°; L. P. Cailletet and E. Mathias, 1.057 at 34°; 0.910 at -1.6°; and 0.76 at 22.2°; and B. Schwalbe, 0.83 at 0°. E. H. Amagat found the sp. gr. of liquid and gas converged as the temp. approached the critical point, when the two coincided:

	0°	10°	20°	30°	30.5°	31°	31.35°
Liquid	0.914	0.856	0.766	0.589	0.574	0.536	0.464
Gas	0.096	0.133	0.190	0.331	0.356	0.392	0.464

J. Timmermans measured the sp. gr. of liquid carbon dioxide between 0° and the b.p. A. Blümcke measured the density of mixtures of sulphur and carbon dioxides. According to P. Villard and R. Jarry, the sp. gr. of the solid is greater than that of the liquid; H. Landolt gave 1.188 to 1.199 for the sp. gr. of the compressed snow; L. Bleekrode gave 1.3 to 1.6; B. Schwalbe, 1.19. By subliming solid carbon dioxide in a vessel cooled below -79°, U. Behn obtained the solid as a clear glass of sp. gr. 1.56; and he obtained 1.53 for the sp. gr. of the snow suspended therein; J. P. Kuenen and W. G. Robson, 1.48; J. Dewar, 1.6267 at -188.8°; and 1.53 at the b.p.

The molecular volume, according to L. Meyer,⁴ is 26.7; and A. Naumann also gave a value for this constant. D. Berthelot gave 0.99326 for v_0 in the equation $v_0 = (vp/p_0) \{1 + a(p - p_0)\}$, where a is a constant, v the vol. under a very small press. p , and p_0 is the normal press. P. N. Pavloff discussed the relations $T_c = 1.610 M/n^2$, where n denotes the number of atoms per mol. Values for the specific volume of carbon dioxide vap. were obtained by L. P. Cailletet and E. Mathias, U. Behn, J. J. van Laar, E. H. Amagat, and C. F. Jenkins and D. R. Pye—*vide* Table XXIII. According to F. G. Keyes and A. W. Kenney, the sp. vols. of the vap. in c.c. per gram are:

	-50°	-40°	-30°	-20°	0°	10°	20°	30°	30.2°
Sp. vol.	57.32	38.02	27.44	19.72	14.02	10.44	7.561	5.319	3.70

The sp. vols. of the liquid in c.c. per gram have been measured by L. P. Cailletet and E. Mathias, U. Behn, and E. H. Amagat. The following data at 10° and downwards are by U. Behn, and those above 10° by E. H. Amagat:

	-50°	-40°	-30°	-20°	-10°	0°	10°	20°	30°
Sp. vol.	0.8665	0.8960	0.9302	0.9699	1.019	1.081	1.163	1.305	1.672
α	308.4	313.2	319.2	320.4	323.2	325.5	326.8	324.7	315.3

F. G. Keyes and A. W. Kenney found that data are then well represented by $v = 2.7986 - \log(\alpha - T)$; and if D_1 be the density of the vap., and D_2 that of the liquid, the mean density equation is $\frac{1}{2}(D_1 + D_2) = 0.4597 + 0.00179(T_c - T) - 0.0000041(T_c - T)^2$.

The molecular weight calculated by D. Berthelot is 44.000; Lord Rayleigh obtained 44.268 at 0° and atm. press., and 44.014 at small press. ($O = 32$); A. Jaquerod and F. L. Perrot gave 43.902 at 1067°; and L. Löwenstein, 43.8 at 1350°. H. von Jüptner observed no appreciable mol. association in liquid carbon dioxide. H. Kolbe represented the mol. by the formula $(C_2O_2)_2$; and L. Zeschko made some observations on this subject. J. C. Maxwell gave 9.3×10^{-10} mm. for the

diameter of the molecule; J. H. Jeans gave 4.56×10^{-8} mm.; E. Dora, and A. von Obermayer made estimates of this constant. C. E. Guye calculated the mol. diameter from the electromagnetic rotation. J. H. Jeans gave 4.0×10^{-6} cm. for the **mean free path**. J. C. Maxwell estimated the **collision frequency** to be 9.2×10^8 per sec. P. Blaserna found the **molecular velocity**, V , in metres per sec.

Press.	0	74	100	500	1000	1500	2000 cms.
V at 3.3°	393.3	392.1	391.8	385.0	374.5	362.9	350.4
V at 100°	459.7	459.2	459.0	456.4	452.8	449.4	446.2

A. Eucken infers that in the mol. of carbon dioxide, the carbon atom lies almost in a line joining the oxygen atoms and that it executes small elastic circular vibrations about them. M. F. Skinner investigated the motion of electrons in carbon dioxide. The **moment of inertia** perpendicular to the line joining the oxygen atoms is about 50×10^{-40} gm. per sq. cm., and the mutual separation of the oxygen atoms is about 2×10^{-8} cm. J. E. Mills studied the **molecular attractions** of liquid carbon dioxide. J. A. Muller estimates the degree of polymerization of carbon dioxide in the critical state to be 1.351. C. Ramsauer estimated the effective diameter of the molecules towards slow electrons. R. Gans discussed the symmetry of the mol. of carbon dioxide; and A. E. Oxley, A. O. Rankine, E. D. Eastman, A. W. C. Menzies, and A. Eucken, the electronic structure of the molecule—*vide* 4. 27, 4; H. F. Meyer, the action of slowly moving electrons of the carbon dioxide molecule; and L. B. Loeb, the affinity of the mols. for electrons.

According to W. Crookes,⁵ the **viscosity** of carbon dioxide decreases very rapidly between 620 mm. and 50 mm. press., and between 760 mm. and 1 mm., the decrease is twice as great as in air. The viscosity, η , of carbon dioxide has been determined over the range -21.5° and 302° by a number of different investigators—A. Kundt and E. Warburg, E. Warburg and J. Sachs, O. Schumann, S. Pagliani and A. Batelli, Y. Ishida, L. J. Lassalle, O. E. Meyer and F. Springmühl, etc. O. E. Meyer gave 0.000160 to 0.000168 at 0° ; A. Klemenc and W. Remi, 0.0001382 at 0° ; and A. Wüllner, 0.0001383 at 0° and 0.0001859 at 100° . The values increase with rise of temp.

	-21.5°	0°	15°	50°	100°	182.4°	246.3°	302°
$\eta \times 10^7$	1278	1414	1488	1579	1638	1916	2221	2458

In W. Sutherland's formula $\eta = \eta_0 \{ (273 + T)/(T + C) \} \{ T/273 \}^1$, for the relation between the viscosity of a gas and temp., C has the value 277 for carbon dioxide; P. Breitenbach gave 239.7; and A. Klemenc and W. Remi, 263.4. The effect of air on the density and the viscosity was determined at different temp. and press. by E. Warburg and L. von Babo in 1882. P. Phillips determined the viscosity—*press. isothermals*, at 20° , 30° , 32° , 35° , and 40° . Some of the measurements are shown in Table XXII, and the results are plotted in Fig. 45. The form of the viscosity-

TABLE XXII.—THE EFFECT OF PRESSURE ON THE VISCOSITY AND DENSITY OF CARBON DIOXIDE.

20°			32°			40°		
Press. p atm.	Viscosity η .	Density D.	Press. p atm.	Viscosity η .	Density D.	Press. p atm.	Viscosity η .	Density D.

56	186	0.190	84	560	0.682	80	218	0.291
50	177	0.145	70	244	0.255	70	200	0.204
40	166	0.100	60	187	0.170	60	187	0.153
20	156	0.036	20	162	0.0352	23.8	169	0.0408
1	148	0.00183	1	155	0.00176	1	157	0.00173

press. isothermals is very similar to the density-press. isothermals except that the former cross one another, while the latter do not. This is due to the fact that the viscosity of a gas increases with a rise of temp., whereas the viscosity of a liquid decreases with rising temp. The curves cross before the gas is liquefied, showing that it is beginning to act like a viscous liquid before condensation occurs. The critical viscosity is 0.321×10^{-3} , and the critical density 0.464. The portions *AB* and *A'B'* represent the viscosity of a superheated liquid, while *CD* and *C'D'* represent the viscosity of a supercooled vap. By plotting the density-viscosity curves, the points corresponding with different temp. run along curves very close together, showing that in the range of temp., 20°-40°, of these experiments, the viscosity depends almost entirely on the density. By plotting the square of the densities between 0.2 and 0.7, the viscosity is a linear function of the square of the density, meaning that within this region of rapid variation of density with temp. or press., "the change in viscosity is almost entirely due to the change in attraction between two adjacent layers of the fluid, for this would be proportional to the square of density. In other words, the viscosity in this region depends almost entirely on the term a/v^2 in J. H. van der Waals' equation. At higher densities, it is probable that the change in the kinetic energy of the mol. begins to play a larger part, and at low densities, the attraction between the mols. becomes quite negligible." The coefficient of slip—vide hydrogen—is $\gamma = 0.00000650$. J. Puluj measured the viscosity of mixtures of carbon dioxide and hydrogen, and found a maximum with the mixture $\text{CO}_2 + 0.3\text{H}$; with $\text{CO}_2 + 6\text{H}$ the viscosity is the same as that of pure carbon dioxide; and the values then decrease regularly with increasing proportions of hydrogen. E. Warburg and L. von Babo found the sp. gr., *D*, and viscosity, η , of liquid carbon dioxide to be:

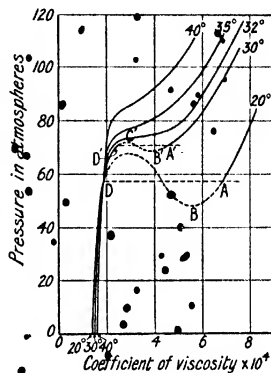

FIG. 45.—Viscosity-Pressure Isothermals of Carbon Dioxide.

	5°	10°	15°	20°	25°	29°
<i>D</i>	0.922	0.895	0.864	0.827	0.783	—
$\eta \times 10^6$	925	852	784	712	625	539

C. J. Smith showed that the viscosity of a mixture of nitrous oxide and carbon dioxide in C.G.S. units is 0.0001366 at 0°; 0.0001441 at 15°; and 0.0001845 at 100°. The mean collision area was calculated to be 0.834×10^{-15} sq. cm. J. E. Verschaellé found the capillary constant, a^2 , and the surface tension, σ , of liquid carbon dioxide to be:

	—24.3	8.9	15.2	20.0
a^2	1.950	0.821	0.685	0.375 sq. mm.
σ	9.21	2.90	1.82	1.00 dynes per cm.

The velocity of sound in carbon dioxide at 0° has been measured by W. J. M. Rankine, C. Bender, C. T. Knipp and W. B. Worsham, P. L. Dulong, A. Masson, I. B. Zoch, T. Martini, H. B. Dixon and co-workers, and A. Wüllner; and at 10°-24°, by J. W. Low. According to O. Buckendahl, the velocities in metres per second at different temp. are:

Velocity	0°	100°	300°	500°	670°	947°	1080°
	258.04	301.59	373.74	434.06	503.28	543.29	572.45

J. L. M. Poiseuille⁷ computed the speeds at which water and a sat. aq. soln. of carbon dioxide passed through capillary tubes. T. Graham measured the rate of transpiration of carbon dioxide under similar conditions, and found that if the time,

for oxygen be unity, that for carbon dioxide is 0.7272; and for the effusion of carbon dioxide into a vacuum, 1.573 when that for oxygen is unity. W. Timofejeff made some measurements on this subject; and F. G. Donnan found that the rate of effusion of carbon dioxide is about one per cent. in excess of that calculated from T. Graham's law. K. Sameshima and K. Fukaya studied the atmolysis of carbon dioxide. The throttling experiments producing the so-called **Joule-Thomson effect** were found by J. P. Joule and W. Thomson, at about 3 atm., to be 1.34 at 7.4°, 1.03 at 35.6°, 0.89 at 54.0°, and 0.65 at 97.55°; C. F. Jenkin and D. R. Pye found at 40.8 atm. press., 1.091 at 29.5°, 1.62 at 24.5°, and 1.242 at 20°. E. Natanson found at 25°, 1.18 at 0 atm., 1.30 at 10 atm., 1.43 at 20 atm., and 1.50 at 25 atm. F. E. Kester represented their results at 22°, by $d\theta/dp = 1.187^\circ + 0.0015p$. The variation of $d\theta/dp$ with p is greater than would follow from J. D. van der Waals' equation. W. A. D. Rudge measured the effect at 21° with a difference of press. of 57° to be -1.85° per atm. difference of press. M. Jakob found the press., p , and temp., T , at which the differential Joule effect is zero, is $(dv/dT)_{p,v} = v/T$; and that $p = 899.7 - 1.167T - 1102 \times 10^{-4} T^2$. E. S. Burnett, and F. G. Keyes also studied the effect with carbon dioxide.

J. Loschmidt's values* for the **diffusion coefficient**, k , per sq. cm. per sec. of carbon dioxide and

	N ₂ O	CO	O ₂	Air	CH ₄	H ₂
k	0.09831	0.14055	0.14095	0.14231	0.15856	0.55585

A. von Obermayer gave values for carbon dioxide with nitrous oxide, ethylene, methane, carbon monoxide, air, oxygen, and hydrogen; A. Lonius, and R. Lorenz and A. Magnus, for hydrogen; J. Stefan, for water, and alcohol; A. Winkelmann, and G. Guglielmo, for water vap.; K. Waitz, V. Hausmaninger, J. C. Maxwell, J. J. Hood, H. T. Brown and F. Escombe, for air; G. Hüfner, for carbon monoxide; A. Winkelmann, for alcohol, ether, esters, and fatty acids. A. von Obermayer represented the effect of temp. and press. with air, oxygen, and nitrous oxide by $k_0 = k(T_0/T)^{1.75} p/76$; J. Loschmidt used $k_0 = k(T_0/T)^2 p/76$ for a number of gases. According to R. Brimmeyr, when carbon dioxide is separated from hydrogen or oxygen by a moist bladder, more carbon dioxide diffuses to the specifically lighter gas than conversely; and with a dry porous partition, less carbon dioxide diffuses to the specifically lighter gas than conversely. J. Wiesner and H. Molisch also found that carbon dioxide diffuses through vegetable membranes more rapidly than hydrogen, oxygen, or nitrogen. T. Graham, and C. Matteucci studied the rate of diffusion of carbon dioxide through dry plaster of Paris; H. E. Roscoe, and M. Pettenkofer, through bricks; and F. Hannen, through soils. L. Pfandler, and G. Quincke found that carbon dioxide under press. does not diffuse perceptibly through glass walls 1.5 mm. thick. T. Graham, J. Dewar, and E. Obach measured the diffusion of carbon dioxide through caoutchouc or rubber, and the first named found that the rates with carbon dioxide and monoxide are as 13.585:1.113. F. Kolbe found 0.003 c.c. of the gas passes per hour through a sq. cm. of rubber 2 mm. thick; and H. Kayser found the speed to be much less than that of hydrogen, and to increase proportionally with temp., while the absorption coeff. decreases with temp.—*vide infra*. L. L. Grunmach showed that the increase in the rate of diffusion through rubber is not proportional to the difference of press., and that the decrease in the rate is not proportional to the thickness of the membrane.

R. Fricke⁹ investigated the growth in the size of bubbles of carbon dioxide rising in liquids. F. J. Wrede showed that Boyle's law does not describe the behaviour of carbon dioxide at elevated press., and H. V. Regnault found the gas to be more compressible than is represented by the function $(p_0 p_0 / vp) - 1 = 0$, and he represented the compressibility by an interpolation formula; so also did A. Avogadro. E. Mascart gave 0.00901 for the compressibility at 3°; D. Berthelot, 0.00688 between 1 atm. and 2 atm., between 1 and 0.5 atm., 0.00676, and between 0.5 and 0.25 atm., 0.00666. P. A. Guye and T. Batuecas gave 0.00706 ± 0.00004 for the compressibility

coeff. W. H. Kleson, T. Andrews, and Lord Rayleigh also measured the compressibility of this gas. T. Andrews' observations on the pT -curves of carbon dioxide have been discussed previously (p. 48); and C. G. Knott has compiled the data from T. Andrews' note-books. E. H. Amagat gave for the change of compressibility pv/p_1v_1 with temp., when the value of pv at 0° and 1 atm. press. is unity.

		50°	100°	200°	300°
Press.	0.725 atm.	1.0037	1.0021	1.0009	1.0003
	1.440 atm.	1.0075	1.0048	1.0025	1.0015
	2.880 atm.	1.0145	1.0087	1.0040	1.0020

E. H. Amagat, H. V. Regnault, K. Neumann, and P. Blaserna measured the deviations from Boyle's law exhibited by this gas. E. H. Amagat's results are given in Table XXIII. The results are plotted in Fig. 46, where the inset represents the

TABLE XXIII.—E. H. AMAGAT'S VALUES FOR THE PRODUCT pv
($pv = \text{UNITY AT } 0^\circ \text{ AND } 1 \text{ ATM. PRESS.}$)

Press. atm.	Temperatures.

curves for values of p between 25 and 125 atm. on a magnified scale. It will be observed that the value of pv at a given temp. falls to a minimum and then rises again. The press. p atm. at which pv reaches a minimum at different temp. are

	0°	10°	20°	40°	60°	80°	100°	137°	198°	258°
p	35	45	57	101	143	179	211	247	255	218

These results mean that the compressibility reaches a maximum and then diminishes again. The minimum, Fig. 46, at the higher press. is flatter and less abrupt. The curve at the highest temp. is not parallel to the abscissa-axis as would be the case if $pv = \text{constant}$. From the inset of Fig. 46, it follows that below the critical temp. the press. remains constant for certain values of pv . This means that the gas has partly liquefied, and the vap. press. of the liquid at the given temp. is being measured. The deviations from Boyle's law have been discussed by J. A. Siljeström, D. I. Mendeleff, P. Blaserna. T. Batuecas represented the deviation from Avogadro's law by $1 + \lambda = 1.00706$. F. G. Keyes discussed the error in the measurements produced by the adsorption of carbon dioxide by the glass. A. Wohl,

and R. Wegscheider studied the applicability of an amended gas equation. In the vicinity of the critical temp., the values of pv are as follow (when pv at 0° and 1 atm. press. is unity):

p	70	71	72	73	74	75
at 30°	0.470	0.230	0.223	—	0.219	0.219
at 32°	0.540	—	0.491	0.460	0.405	0.268
at 38°	0.602	—	—	—	0.531	0.510

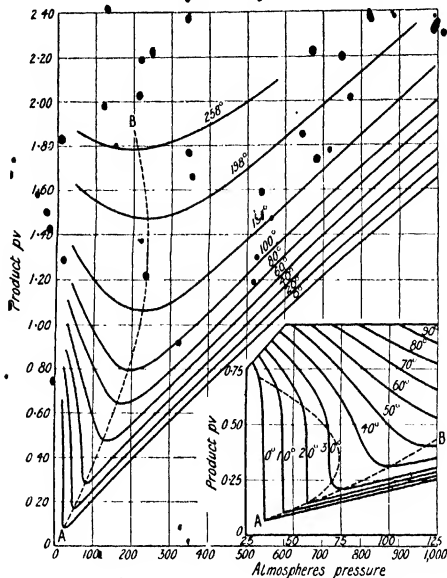

FIG. 46.—Isothermal Pressure and pv -curves of Carbon Dioxide at Different Temperatures.

W. H. Keesom measured the compressibility of mixtures of carbon dioxide and oxygen; T. Andrews, of mixtures of carbon dioxide and nitrogen; A. Thiel and E. Schulte, R. Pietet, F. Braun, and A. Blümcke, of mixtures of carbon dioxide and sulphur dioxide; J. P. Kuenen, of mixtures of carbon dioxide and methyl chloride; A. Thiel and E. Schulte, of binary mixtures of carbon dioxide with ethyl chloride, methyl ether, ethyl ether, chlorine, or hydrogen sulphide; and J. Dewar, of binary mixtures of carbon dioxide with bromine, hydrogen chloride, carbon disulphide, chloroform, methyl chloride, carbon tetrachloride, benzene, acetylene, ether, camphor, nitrous oxide, and phosphorous trichloride—vide chemical properties of carbon dioxide.

T. Andrews emphasized the high compressibility of liquid carbon dioxide; and J. Natterer said that it has a greater compressibility than that of any other liquid yet tried. C. F. Jenkin investigated the compressibility of liquid carbon dioxide; and C. A. Parsons compressed the liquid one-fifth of its vol. by a press. of 30 tons per sq. in. According to W. P. Bradley, A. W. Browne, and C. F. Hale, when a system containing both liquid and gaseous carbon dioxide between temp. of 29° and 31.2° is subjected to proper mechanical vibration, a peculiar **log-effect** is produced. This is due not to impurities in the gas, but to a change of state in the liquid and vap. phases, resulting respectively in the formation of minute bubbles and drops. The change of state is produced by alternate compression and dilatation effected by the vibrations of a steel rod clamped to the press. jacket of the apparatus. Under given conditions of temp., press., length of mercury column, and relative vol. of the

press., vibrations of a certain definite pitch are required in order to produce the fog effect.

The vapour pressure of liquid carbon dioxide has been measured by M. Faraday,¹⁰ H. V. Regnault, R. Mollier, E. H. Amagat, T. Tate, P. Blaserna, L. P. Cailletet, H. du Bois and A. P. Wills, P. Villard and R. Jarry, J. Verschaffelt, J. Zeleny and R. H. Smith, C. Antoine, A. Jarolimek, etc. H. V. Regnault represented his results at θ° between -25° and 45° by $\log p = 5.6771989 - 2.2651888\alpha\theta^{+26} + 0.6888035\beta\theta^{+26}$, where $\log \alpha = 9.9947089 - 10$, and $\log \beta = 9.9916406 - 10$. C. Antoine used the formula $\log p = 0.8118(9.2615 - 1000(\theta + 263)^{-1})$; and A. Jarolimek, $\theta = 63p^{0.25} - 2.5p^{+1} - 154.5$. F. Henning and A. Stock gave between 10° and -181° , $\log p = -1279.11T^{-1} + 1.75 \log T - 0.0020757T + 5.85242$. F. G. Keyes and A. W. Kenney used $\log_{10} p = 12.0722 - 1496.7T^{+1} - 0.028453T + 0.000364T^2$; and for the rate of change of press. with temp., $dp/dt = p(3446.3T^{-2} + 0.0001676T - 0.065527)$. F. G. Keyes and A. W. Kenney gave:

	-50°	-40°	-30°	-20°	-10°	0°	10°	20°	30°
p	6.63	9.90	14.08	19.40	26.07	34.28	44.31*	57.03	71.25
dp/dT	0.2726	0.3660	0.4722	0.595	0.739	0.906	1.104	1.353	1.624

E. Falck represented the vap. press., p , of the liquid by $\log_{10} p = -4970/4.571T + 1.75 \log_{10} T - 0.03239T/4.571 + 3.17$. J. P. Kuentzen and W. G. Robson's values for the vap. press. of solid and liquid are:

	78.32°	-75°	-70°	-60°	-55°	-50°	-40°	-20°	0°
p (solid)	1.00	1.28	1.88	3.97	—	—	—	—	—
p (liquid)	—	—	—	4.30	5.35	6.60	9.82	19.3	34.3

H. L. Callendar used $\log_{10} p = 2.7033 + 3.157/\theta T$ in atm. of 760 mm. (latitude 45°), which is the simplest possible formula; A. Stock and co-workers used $\log p = -1279.11T^{-1} + 1.75 \log T - 0.0020757T + 5.85242$ between -78° and -110° . E. Falck represented the vap. press., p , of the solid by $\log_{10} p = -6000/4.541T + 1.75 \log_{10} T - 0.009982T/4.541 + 3.17$. J. Zeleny and R. H. Smith obtained for the vap. press. p cm. of the solid:

p	-56.4°	-57°	-60°	-70°	-80°	-90°	-100°	-120°	-134°
	391	368.5	343	144	65.7	28.8	11.9	1.4	0.1

H. K. Onnes and S. Weber measured the vap. press. of carbon dioxide down to -183° , and found the results in agreement with E. Falck's formula. A. Stock recommended carbon dioxide as a liquid for thermometers over the range -73° to -100° . R. Lorenz studied the theory of the subject.

The coefficient of thermal expansion, α , at constant press. has been measured by G. Magnus,¹¹ who found $\alpha = 0.00369087$ between 0° and 100° ; H. V. Regnault, $\alpha = 0.003710$, and at constant vol., $\beta = 0.003688$ between 0° and 100° . Values were also obtained by W. J. M. Rankine, P. von Jolly, T. Andrews, J. Moutier, E. Natanson, A. Cazin, V. Meyer, F. Roth, E. H. Amagat, etc. A. Jaquero and F. L. Perrot obtained at constant vol. between 1° and 1067° , $\beta = 0.0036756$ with the initial press. 240 mm. at 0° ; and $\beta = 0.0036713$ with the initial press. 170 mm. at 0° . G. Melander found at constant vol., at p mm. press.

p	18.1	55.8	101.5	169.1	267	347	740
α	0.0036753	0.0036641	0.0036657	0.0036701	0.0036803	0.0036856	0.0037264

A. Leduc gave $\alpha = 0.003724$ between 0° and 100° at constant press., and $\beta = 0.003713$ at constant vol.; or $\alpha = 0.003750$ at 0° , and $\beta = 0.003725$ at 0° . P. Chappius found for the coeff. of expansion, α , at constant press.:

		0° to 20°	0° to 40°	0° to 100°
α	518 mm.	0.0037128	0.0037100	0.0037073
	999 mm.	0.0037602	0.0037536	0.0037410
	1377 mm.	0.0037972	0.0037906	0.0037703

F. H. Amagat found at constant press., $\alpha \times 10^3$ to have at p atm. press. and between 0° and 258° , the values indicated in Table XXIV. The thermal expansion of

TABLE XXIV.—COEFFICIENTS OF EXPANSION OF CARBON DIOXIDE AT DIFFERENT TEMPERATURES AND PRESSURES.

Press. atm.	Temperatures.													
	10°	20°	30°	40°	50°	60°	70°	80°	90°	100°	197°	198°	258°

200	416	422	483	529	597	682	781	893	1000	1115	1349	1631	1593	
500	253	267	271	278	292	305	316	337	337	349	387	449	—	
1000	175	181	183	185	189	190	194	198	202	206	226	—	—	

liquid carbon dioxide is stated by J. H. Niemann to be greater than that of any substance yet observed; B. Schwalbe also emphasized the large coeff. of expansion. J. Dewar found that the coeff. of expansion of the liquid at the b.p. 0.00299 is very nearly five times the value of the coeff. of the solid between -188° and the b.p. E. d'Andréff found that if the vol. at 0° is unity, the vol. at -10° is 0.9517 ; at $+10^\circ$, 1.0585 ; and at 20° , 1.1457 . J. Dewar gave 0.0005704 for the coeff. of expansion of solid carbon dioxide between -188° and the b.p. J. D. van der Waals, R. Clausius, L. Schames, A. Ritter, E. Sarrau, K. Langen, W. Schütt, A. Leduc, B. Leinweber, V. Njegovan, J. B. Goebel, V. Fischer, J. Daclaux, etc., have discussed the equation of state of carbon dioxide. R. Clausius' and J. B. Goebel's equations are respectively:

$$p = \frac{0.0036887}{v - 0.000843} - \frac{2.0935}{T(v - 0.000977)}; \quad p = \frac{0.0036847}{v - 0.00329} - \frac{0.00917}{(v - 0.00068)^2}$$

J. D. van der Waals' equation has been previously discussed:

$$\left(p + \frac{0.00891}{v^2}\right)(v - b) = 1.00646 + \frac{T}{273}$$

The values from T. Andrews' data are $a=0.00678$ to 0.00717 , $b=0.001807$ to 0.001908 ; from E. H. Amagat's data, $a=0.00719$, and $b=0.001912$; and from J. Dewar's data, $a=0.00683$, and $b=0.001813$. F. B. MacDougall's calculations of the variations in a and b from E. H. Amagat's data have been indicated (1. 13, 4). H. von Jüptner found the values of b are variable with temp. and internal press., and possibly also with the attraction of neighbouring mols. From E. H. Amagat's data at 100° :

p	50	100	300	500	700	900	1000
a	0.02413	0.01030	0.00297	0.002401	0.002183	0.002051	0.001980
b	0.00298	0.00276	0.00191	0.00172	0.00164	0.00159	0.00156

A similar variation occurs with T. Andrews' data. The variations in the values of b in the neighbourhood of the critical temp. are considerable; but F. Roth showed that over 100° , b is constant.

The thermal conductivity of carbon dioxide has been measured by J. Stefan,¹² A. Winkelmann, A. Wülher, L. Graetz, G. W. Todd, F. Soddy and A. J. Berry, J. Jamin and F. Richard, A. Oberbeck, F. Narr, A. Kundt and E. Warburg, etc. P. A. Eckerlein found for the coeff. k cal. per cm. for 1° , 0.0002546 at -78.5° ; 0.0002824 at -50.5° ; and 0.0003434 at 0° ; A. Winkelmann found 0.000307 at 0° ; and A. Schleiermacher, 0.000327 at 0° and 0.000506 at 100° . E. Pauli found for the ratio k_{100}/k_0 1.418 . S. Weber gave 3.393×10^{-5} . E. Mallard and H. le Chatelier studied the rate of cooling of carbon dioxide.

In 1797, Count Rumford¹³ described experiments on the explosion of gunpowder in a cylinder with a capacity equal to the vol. of the explosive, and fitted with a valve. He said:

What was very remarkable in all these experiments, in which the generated elastic vap. was completely confined, was the small degree of expansive force which this vap. appeared to possess, after it has been suffered to remain a few minutes, or even only a few seconds, confined in the barrel; for upon raising the weight by means of its lever, and suffering this vap. to escape, instead of escaping with a loud report it rushed out with a hissing noise, hardly so loud or so sharp as the report of a common air-gun, and its effects against the leather stopper, by which it assisted in raising the weight, were so very feeble as not to be sensible.

M. Faraday takes this to mean that the carbon dioxide and other gases were condensed to the liquid state. In 1823, H. Davy said that in attempting to liquefy carbon dioxide by a method analogous to that which he employed for hydrogen chloride, by the action of sulphuric acid on ammonium carbonate in a sealed tube, "in the only trial I have made, the tube burst." M. Faraday, however, used the same reaction and condensed the gas to a limpid colourless liquid. He said that much stronger tubes are needed for carbon dioxide than for other gases previously tried:

Tubes which have held liquid carbon dioxide well for two or three weeks together, have, upon some increase in the warmth of the weather, spontaneously exploded with great violence; and the precautions of glass masks, goggles, etc., which are at all times necessary in pursuing these experiments, are particularly so with carbon dioxide.

J. H. Niemann said that it is best to allow the acid to come in contact with the carbonate very slowly because of the development of heat in the reaction. G. Gore closed the tube with a rubber stopper. A. Loir and C. Drion cooled the gas by evaporating liquid ammonia over sulphuric acid under reduced press., and found it liquefied at ordinary press. In 1834, M. Thilorier liquefied the gas by compression in a pair of cast-iron vessels, one of which was used for generating and the other for liquefying the gas. He relied on press. alone to produce liquefaction. According to A. Pleischl, in 1835 one of the storing vessels used by M. Thilorier at the École de Pharmacie, Paris, exploded before the class, and, said J. von Liebig, "its fragments were scattered about with the most tremendous force; it cut off both the legs of the unfortunate operator, M. Hervey, and the injury was followed by his death" (1. 13, 25). Wrought-iron was then employed; J. Mareska and E. Donny used lead cylinders surrounded by copper jackets. W. N. Hill, L. P. Caffletet, A. Zimmermann, H. Gall, J. K. Mitchell, H. Debray, R. Addams, J. O. Natterer, have also indicated processes for the liquefaction of the gas. A. Thiel described the filling of glass tubes with liquid carbon dioxide. Numerous systems have been devised for liquefying carbon dioxide, particularly since liquid carbon dioxide is stored and sold in the liquid form. The modern compressors are usually of the multi-stage type in which the gas is compressed in a number of stages involving two, three, or four increases of press. Since the temp. of the gas is raised by compression, the gas is cooled by cold water between each stage. According to R. T. Stewart, and A. Lange, the cylinders in which the gas is stored are not completely filled, a space is left for the liquid to expand, otherwise there is a risk of explosion. The presence of air also increases the risk of explosion, for one per cent. of air in the cylinder increases the press. by three per cent. under the most favourable conditions.

J. Behrens, R. Mackenzie, F. Windhausen, H. Herberts, P. Winand, etc., have patents on the preparation of the liquid; and O. M. C. Heyl, A. Knöpp, W. Burstyn, A. Müller, P. Pagottet, etc., have discussed the holders for storing the liquid. There are a number of monographs on the subject: E. Luhmann, *Die Kohlensäure*, Wien, 1906; *Die Fabrikation der flüssigen Kohlensäure*, Berlin, 1904; J. C. Goosmann, *The Carbonic Acid Industry*, Chicago, 1907; O. Kausch, *Die Kohlensäure, ihre Herstellung und Verwendung*, Hanover, 1909; N. Wender, *Die Kohlensäure Industrie*, Berlin, 1901; A. M. Villon, *Les emplois industriels de l'acide carbonique*, Paris, 1892; T. Koller, *Die Imprägnungstechnik*, Wien, 1896; C. A. Mitchell, *Mineral and Aerated Waters*, London, 1915.

M. Thilorier found that when liquid carbon dioxide is placed in a vessel provided with an opening in the form of a blowpipe jet he was able to produce local cooling effects, and he called the arrangement a *galumeau de froid*—a cold-blast blowpipe. By releasing the gas from press. he obtained snow-like masses which he first thought to be actual snow formed by condensation from the moisture of the air. It was afterwards found that the chilling of the escaping carbon dioxide is so great that some of it becomes solid. J. K. Mitchell obtained the solid in a similar manner. L. Bleekrode recommended preparing the solid from bombs of the liquid gas by the method employed by H. Landolt, etc. A cloth bag is tied to the delivery valve of the bomb, and the solid collects in the bag when the delivery tube is opened. This method is as effective and more simple than the use of special ebonite or-metal boxes—used by E. Ducretet, L. P. Cailletet, etc.—which are liable to have their parts frozen together and then cannot be quickly emptied. C. R. Darling recommended making a flannel bag by rolling coarse flannel round a stout tube or rod and tying up one end. The other end was fixed on to the nozzle of a cylinder of carbon dioxide. When the gas is turned on, a rod of solid carbon dioxide soon forms, and can be easily removed by undoing the bag or cutting it open. O. Hergt, A. Wultze, and N. Tschu have also described the preparation of the solid. A. Loir and C. Drion obtained the solid at about 2 atm. press. by cooling carbon dioxide with liquid ammonia.

H. V. Regnault¹⁴ gave -77.75° to -78.16° for the boiling point of liquid carbon dioxide; M. Berthelot, and B. Schwalbe, -78.2° ; C. S. M. Pouillet, and P. Villard, -79° ; J. P. Kuenen and W. G. Robson, -78.32° ; H. Erdmann, -78° at 760 mm. H. du Bois and A. P. Wills gave -79.2° ; F. G. Keyes and co-workers, -78.53° ; and J. Zeleny and H. H. Smith, 78.2° . K. Scheel represented the effect of press., p mm., on the b.p. by: $B.p. = -78.5 + 0.01595(p - 760) - 0.000011(p - 760)^2$. For the melting point, J. K. Mitchell gave -65° ; M. Faraday, -75° ; P. Villard and R. Jarry, -56.7° at 5.1 atm. press.; B. Schwalbe, -57° at 5.3 atm. press., and -63.9° at 3.6 atm. press.; and H. Erdmann, -57° . J. P. Kuenen and W. G. Robson found the m.p. is displaced 1° by 47.9 atm. press. G. Tammann measured the effect of press. on the m.p.; and P. W. Bridgman found that the m.p. at one atm. press. is -56.6° , and for press. in kgms. per sq. cm., the m.p. is

Press. . .	1000	2000	3000	4000	5000	6000	7000	12,000
M.p. . .	-37.3°	-20.6°	-5.3°	8.5°	21.2°	32.9°	44.0°	93.6°
δv . .	—	—	0.1071	0.0979	0.0896	0.0822	0.0755	0.0531

The change of volume on freezing is represented by δv . The results are plotted in Fig. 47.

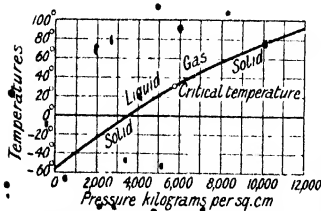

FIG. 47.—The Effect of Pressure on the Melting Point of Carbon Dioxide.

the solid sublimates or passes directly into the gas, and the curve represents the equilibrium between the solid and gaseous carbon dioxide. There is no break in the curve at the critical temp. of the liquid, above 31° , so that a mere change of press. will suffice to pass from the gas to crystalline solid. This suggests the questions: Can all gases at ordinary temp. be converted into solids by the mere application of a large enough press. without their assuming the liquid state? Can

M. Faraday pointed out that owing to the high vap. press. of liquid carbon dioxide, it gives the paradoxical result that if the b.p. be defined as the temp. at which the vap. press. of the substance just balances that of the atmosphere, the b.p. of carbon dioxide is lower than its f.p. by about 22° . J. Johnston has drawn attention to the fact that at about 5800 atm. press., the melting temp. of the solid is the same as the critical temp. of the liquid; at press. higher than this,

water above its critical temp. be solidified by press. alone? Can H_2O be solidified at ordinary temp. by mere compression?

The triple point, according to J. Zeleny and R. H. Smith, is -56.4° at 5.1 atm. press.; J. P. Kuenen and W. G. Robson gave -56.2° at 5.1 atm.; and P. Villard and R. Jarry, -56.7° at 5.1 atm. According to H. du Bois and A. P. Wills, the value of dp/dT at the triple point is 5.5 atm. per degree. The triple point is represented in G. Tammann's equilibrium diagram, Fig. 48, by the point O_1 ; O_1A is the vaporization curve of the liquid; O_1B is the sublimation curve of the solid; and O_1C represents the effect of press. on the m.p. being the boundary line of the solid and liquid phases. The portion O_1C of the O_1C -curve is dotted to show that G. Tammann thought the solid to be in a metastable condition, with a transition point O_4 . The solid stable under ordinary conditions was called *Solid I*, and the second form was called *Solid II*. Later G. Tammann showed that the alleged modification was due to a mal-observation. P. W. Bridgman found no evidence of a second solid phase at 25° and 67° for press. up to 12,000 kgrms. per sq. cm. The diagram is also discussed by H. W. B. Roozeboom.

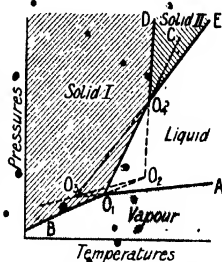

FIG. 48. Equilibrium Diagram of Carbon Dioxide.

T. Andrews found the critical temperature of carbon dioxide to be 30.92° ; E. H. Amagat, 31.35° ; J. E. Verschaefelt, and L. P. Cailletet and co-workers, 31.1° ; E. Sarrau, 32.1° ; J. Chappius, 31.5° ; K. Wesendonck, 31.05° ; J. Dewar, 31.9° ; and E. Cardoso and R. Bell, $31^\circ \pm 0.10$. Other observations have been made by J. B. Hannay, D. Berthelot, J. Jamin, W. Ramsay, G. Owen and A. L. Hughes, H. Happel, W. H. Keesom, H. K. Onnes and G. H. Fabius, E. Cardoso and R. Bell, etc. T. Andrews gave 73 to 77 atm. for the critical pressure; W. H. Keesom, 72.93 atm.; E. H. Amagat, 72.9 atm.; E. Sarrau and J. Dewar, 77.0 atm.; and E. Cardoso and R. Bell, 72.85 ± 0.10 atm. According to L. P. Cailletet, when a mixture of air and carbon dioxide is submitted to press., the liquefaction of the carbon dioxide is often greatly retarded. Thus, a mixture of equal vols. of air and carbon dioxide will support a press. of 400 atm. at 21° without visible change. When, however, 5 vols. of carbon dioxide are mixed with 1 vol. of air, the former is easily liquefied. If the press. be then raised to 150 or 200 atm., the meniscus of liquefied acid, before concave and well-defined, grows flat and indistinct, then it gradually becomes imperceptible, and the liquid at length disappears altogether. The tube then appears as if filled with homogeneous matter, which resists all further press. as a liquid would. When the press. is again slowly diminished, the liquid suddenly reappears, at a press. which is constant for given temp. A thick cloud appears in the tube, spreads, and vanishes as the liquid forms. The press. at which the liquid carbon dioxide reappears are at 5.5° , 130 atm.; at 10° , 124 atm.; at 13° , 120 atm.; at 18° , 113 atm.; at 19° , 110 atm. Carbon dioxide gas compressed beyond 250 atm. is not liquefied at 21° . It might be supposed that this disappearance of the liquid is apparent only, in consequence of the refractive index of compressed air increasing more rapidly than that of liquid carbon dioxide, so that at the point where the two indices become equal, the surface of the liquid would cease to be visible; but, in that case, the surface of separation should again become visible when the press. is further increased. This, however, does not occur, and it is inferred that under high press. a gas and a liquid are capable of soln. in each other, so as to form a homogeneous whole. T. Andrews' value for the critical volume of carbon dioxide is 0.0066 and W. H. Keesom's 0.00443; and E. H. Amagat's value for the critical density is 0.464. T. Andrews gave 0.30, E. Sarrau, 0.4395; J. Dewar, 0.65; L. P. Cailletet and E. Mathias, 0.46; W. H. Keesom, 0.469; and H. K. Onnes and G. H. Fabius, 0.460. S. F. Pickering gave for the best representative values $t_c = 31.1^\circ$; $p_c = 72.9$ atm.; and $D_c = 0.460$. E. E. Walker estimated

the mol. association at the critical temp. to be 1.012; and $4RT_c/15p_c v_c = 0.957$. G. Bakker calculated the thickness of the capillary film between homogeneous phases of the liquid and vapour of carbon dioxide.

Thickness	-30°	-10°	0°	10°	20°
	1.46	1.7	2.0	2.6	3.6 mμ. layers

G. Ansdell, J. D. van der Waals, and J. Dewar measured the effect of *hydrogen chloride* on the critical constants of carbon dioxide; J. Jamin, and J. E. Vefschaffelt, of carbon dioxide and hydrogen; W. H. Keesom, oxygen; T. Andrews, and K. Tsuruta, nitrogen; J. Jamin, and U. Lala, air; A. Bluncke, R. Pictet, and F. Caubet, sulphur dioxide (cf. 1, 4, 8); F. Caubet, nitrous oxide; J. P. Kuenen, and J. P. Kuenen and W. G. Robson, ethane; J. Dewar, and J. P. Kuenen, acetylene; L. P. Cailletet and P. Hautefeuille, cyanogen; J. P. Kuenen, and F. Caubet, methyl chloride; and J. Dewar, chloroform, carbon disulphide, ether, benzene, and phosphorus trichloride—vide chemical reactions of carbon dioxide. M. Centnerszwer and M. Zoppi, and E. H. Büchner have studied the effect with a number of organic liquids. P. Kohnstamm and J. C. Reeders studied the condensation phenomena with mixtures of carbon dioxide and urethane.

The heat of vaporization, according to J. Chappuis,¹⁵ is 56.2 cal. per gram at 0° and one atm. press.: B. Schwalbe gave 50.75 cal. at 6.6°. E. Mathias gave 50.76 cal. at 6.5°; 31.80 cal. at 22.04°; and 14.40 cal. at 29.85°. L. P. Cailletet, and E. Mathias gave 11.60 cal. at 30°. The heat of vaporization, added E. Mathias, is zero at the critical temp. C. F. Jenkin and D. R. Pye gave for the heat of vaporization, Q , cal. per gram.

Q	-50	-40°	-30°	-20°	-10°	0°	10°	20°
	79.9	75.7	71.3	66.5	60.9	54.1	46.2	36.5

J. P. Kuenen and W. G. Robson obtained 121 cal. at the b.p., 95.3 cal. at -65.7°, 56.0 cal. at 0°, and 86.1 cal. at the triple point. U. Behn obtained 142.4 cal. at the b.p.; P. A. Favre and J. T. Silbermann, 142.2 cal.; and J. Zeleny and R. H. Smith, 140 cal. R. Mollier, E. Ariès, and K. Langen calculated values for the latent heat of vaporization. L. P. Cailletet gave for the heat of vaporization, Q , of liquid carbon dioxide at θ° between -25° and 31°, $Q = 118.485(31 - \theta) - 0.4707(31 - \theta)^2$. E. Falck gave $Q_c = (4970 + 3.5T - 0.03239T^2)(1 - p/p_c)$, where p_c denotes the critical press., and p the vap. press. of the liquid at T° K. C. F. Jenkin and D. R. Pye gave $\log_{10} Q = 1.164 + 0.4115 \log_{10}(31.5 - \theta)$. F. G. Keyes and A. W. Kenney represented the observed data by $\log_{10} Q = 1.2960 + 0.2221 \log_{10}(T_c - T) + 0.054903 \log_{10}(T_c - T)^2$; and $dQ/dT = -Q\{0.2222 + 0.11 \log_{10}(T_c - T)\}(T_c - T)^{-1}$. The heats of evaporation in cal. per gram; the external work of evaporation $p(v_1 - v_2)$; and the internal energy of evaporation are given in Table XXV. C. Dieterici also studied the inner latent heat of evaporation. P. A. Favre gave 0.3128 cal. per gram for the heat of

TABLE XXV.—THERMODYNAMIC PROPERTIES OF CARBON DIOXIDE.

Temp.	Press. atm.	Sp. vol. of liquid, v_2 c.c. per gram.	Sp. vol. of gas, v_1 c.c. per gram.	Heat of evaporation cal. per gram.	External work of evaporation.	Internal energy of evaporation.	dp/dT

fusion, and 138.7 cal. for the latent heat of sublimation. P. W. Bridgman gave for the latent heat of fusion in kilogram-calories per gram with the press. in kgms. per sq. cm.:

Press.	3000	4000	5000	6000	7000	12,000
Latent ht.	19.92	20.17	21.39	21.77	21.90	22.54

E. Falck represented the heat of sublimation, Q , by $Q = -(6000 + 3.5T - 0.009933T^2)(1 - p/p_c)$, where p_c denotes the critical press., and p the sublimation press. at T° K. U. Behn gave 142.4 cal. for the heat of sublimation. J. P. Kuenen and W. G. Robson gave 129.9 cal. for the heat of sublimation, 43.8 cal. for the heat of fusion. The heat of sublimation at the b.p. is 121 cal., and this increases with rise of temp. W. Nernst gave 3.2 for the chemical constant; E. Falck gave 3.17; and F. G. Henglein, -0.41 .

In 1835, M. Thilorier¹⁶ showed that a mixture of liquid or solid carbon dioxide with ether evaporated rapidly and produced a temp. of -100° . By means of Thilorier's freezing mixture, M. Faraday obtained a temp. of -110° . L. P. Cailliet and E. Colardeau obtained -82° at ordinary press. with a mixture of carbon and nitrogen dioxides; and with methyl chloride, -82° at ordinary press., and -106° in vacuo; P. Villard and R. Jarry studied the mixture with methyl chloride. H. Moissan found that solid carbon dioxide with ethyl or methyl alcohol gives a temp. of -85° ; with methyl chloride or acetaldehyde, -90° ; with ethyl acetate, -95° ; and with acetone, -110° . A. Wohl and M. S. Losanitsch obtained -86° with acetone, and -87° with aldehyde; and P. Villard and R. Jarry obtained no lowering of the temp. with mixtures of carbon dioxide and toluene. The theory of the phenomenon in the light of the phase rule has been discussed by H. W. B. Roozeboom. In Fig. 49, I (78°) represents the sublimation point of solid carbon dioxide at one atm. press.; F represents the b.p. of the alcohol; EDF , the b.p. curve of the mixture; ECF , the vap. curve; and E , the b.p. of undercooled liquid carbon dioxide not experimentally realizable. The b.p., C , of the sat. soln. is always between the boiling and sublimation temp. of the carbon dioxide. If the b.p. E and F are very far apart, the vap. curve ECF is very steep, and it cuts the sublimation curve IC very close to the carbon dioxide axis. Hence, the b.p. of the three-phase system solid carbon dioxide, alcohol and vap., is at A , -80° , near to the sublimation temp. of solid carbon dioxide. The vap. curves of mixtures of carbon dioxide with other substances are not very well known, so that the hypothesis cannot be well tested.

The ratio of the two specific heats of carbon dioxide was determined by H. Buff,¹⁷ who found 1.277; A. Cazin obtained 1.291; A. Masson, 1.277; W. C. Röntgen, 1.3052 (19°); P. A. Müller, 1.2653 between 9.4° and 33.7° and 27.82–75.89 mm.; O. Lummer and E. Pringsheim, 1.296 (4° – 11°); J. W. Low, 1.291 (12° – 20°); E. H. Amagat, 1.292; T. Martini, 1.345 at 0° ; J. Jamia and F. Richard, 1.29; G. de Lucchi, 1.292 (20° – 25°); J. W. Capstick, 1.308 (20°); G. Manœuvrier and J. Fournier, 1.299; W. Makower gave 1.307; A. Kundt, 1.303 (16°); O. Buckendahl, 1.2990 at 0° , and 1.2899 at 1080° ; H. B. Dixon and co-workers, from 1.296 at 0° to 1.230 at 600° ; J. R. Partington, 1.3022 at 17° ; R. Thibaut gave 1.303 (15°); K. Schöler, 1.303 (20°); G. Schweikert, 1.301 (0°); J. R. Partington and H. J. Cant, 1.303 (20°); and B. Törnau, 1.3165 ± 0.0032 at 0° , and H. W. Moody, 1.3003 at 20° and 760 mm. The ratio of the sp. hts. decreases with rising temp., and increases with rising press., so that the two effects work one against the other. A. Wüllner gave 1.311 at 0° , and 1.282 at 100° ; A. Leduc, 1.319 at 0° and 1.283 at 100° .

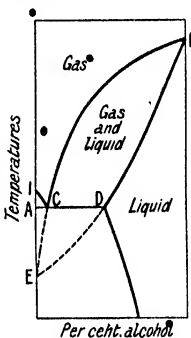

FIG. 49.—Freezing Mixtures of Solid Carbon Dioxide and Alcohol.

J. M. Crofts gave 1.254 between 15° and 532°, 1.253 (15°–545°), 1.252 (15°–557°), and 1.251 (15°–570°); R. Fürstenau gave 1.2506 at 484.5°, and 1.3008 at room temp. R. Thibaut gave 1.300 at 15° and 1 atm. press.; and 1.279 at 20° and one-third atm. press. E. H. Amagat obtained at 50°, 1.705 at 50 atm., 1.903 at 60 atm., and 2.327 at 70 atm. press. According to E. H. Amagat, the ratio of the two sp. hts. increases with rise of press. at constant temp., and decreases with rise of temp. at constant press. A. G. Worthing found at 7.78 atm. press. the ratio is 1.338 at 0.2°, 1.310 at 31°, 1.296 at 50°, and 1.256 at 98.5°; and at 28.52 atm. press., 1.702 at 0.2°, 1.499 at 31°, 1.448 at 50°, and 1.327 at 98.5°. B. Beckman found for the ratio, γ , of the two sp. hts. at press. p mm. at 15°:

p	760	392	244	149	100	76
γ	1.3045	1.301	1.298	1.296	1.303	1.302

W. Kuppe obtained $\gamma=1.300$, and when exposed to X-rays, $\gamma=1.320$, and to ultra-violet light, $\gamma=1.322$.

F. Clément and J. B. Désormes found for the sp. ht. of carbon dioxide at constant press., 0.24; F. de la Roche and J. E. Bérard, 0.2210; J. Apjohn, 0.2094; A. C. G. Supermann, 0.2124; H. N. Mercer, 0.2000; A. de la Rive and F. Marcet, 0.1751; and H. V. Regnault, 0.2164 when referred to equal weights, and 0.3308 when referred to equal vols. H. V. Regnault, H. B. Dixon, E. Wiedemann, W. D. Womersley, etc., observed that the sp. ht. increases with rise of temp. H. V. Regnault gave 0.1870 at 0° and 0.2145 at 100°; and E. Wiedemann gave 0.1952 at 0° and 0.2169 at 100°. H. V. Regnault's data, recalculated by H. F. Weber, referred to equal weights of water, gave 0.1383 between –28° and +7°; 0.1565, between 15° and 99°; and 0.1813 between 12° and 214°. E. Wiedemann found 0.1952 at 0°, 0.2169 at 100°, and 0.2387 at 200°. K. Scheel and W. Heuse gave 0.183 at –78°, and 0.202 at –20°; W. F. G. Swann, 0.202 at 20°, and 0.221 at 100°; L. Holborn and L. Austin, 0.2486 between 20° and 80°, 0.2306 between 20° and 440°, 0.2423 between 20° and 630°; L. Holborn and F. Henning found at 0°, 0.201, and the following values between 0° and θ° , and at θ° , c_θ :

θ	200°	400°	600°	800°	1000°	1200°	1400°	1600°
Sp. ht.	0.215	0.228	0.239	0.249	0.257	0.264	0.270	0.274
Sp. ht. c_θ	0.229	0.252	0.271	0.285	0.295	0.301	0.303	0.300

and he represented the results between 0° and θ° by $c_p=0.2010+0.0000742\theta-0.018\theta^2$; or, according to L. Holborn and L. Austin, the sp. ht. at θ is $c_p=0.2028+0.001384\theta-0.075\theta^2$. T. Martini gave for the molecular heat $C_p=7.89$ at 0°. For the mean mol. heat between 0° and θ° , H. V. Regnault gave $C_p=8.28+0.00596\theta$; E. Wiedemann, $8.56+0.005038\theta$; L. Holborn and L. Austin, $8.92+0.00304\theta-0.079\theta^2$; and L. Holborn and F. Henning, $8.85+0.00327\theta-0.079\theta^2$. For the true mol. heat at θ° , H. V. Regnault's formula becomes $8.28+0.01192\theta$; E. Wiedemann's, $8.56+0.010076\theta$; L. Holborn and L. Austin, $8.92+0.00608\theta-0.0522\theta^2$; and L. Holborn and F. Henning, $8.85+0.00653\theta-0.0624\theta^2$. R. Thibaut gave $C_p=8.77$ at 15°; K. Schöler, 8.76 at 20°; G. Schweikert, 8.85 at 0°; and J. R. Partington and H. J. Cant, 8.76 at 20°. G. N. Lewis and M. Randall gave for the mol. ht. of carbon dioxide between 0° and 2000°, $C_p=7.0+0.0071T-0.00000186T^2$. M. Trautz gave $C_p=8.91+0.0065T$; and S. W. Saunders, for the best representative value, $C_p=7.34+0.003397T-0.00610T^2$. For the increase in the sp. ht. with rise of press., S. Lussana gave 0.201 at one atm., and 0.267 at 30 atm. C. de la Condamine, and V. Fischer calculated values for the sp. hts. at constant vol. and constant press.

H. V. Regnault found the sp. ht. of carbon dioxide at constant vol. to be 0.1843 between –28° and +17°, 0.2025 between 15° and 99°, and 0.2169 between 12° and 214°. L. Holborn and F. Henning gave for the mol. ht. at constant vol. 8.415; F. Keutel, $C_v=6.59$; K. Schöler, 6.72 (20°); R. Thibaut, 6.73 (15°); G. Schweikert, 6.80 (0°); J. R. Partington and H. J. Cant, 6.72 (20°); M. Trautz and O. Grosskinsky, 6.916 (15°), 6.925 (48°), and 6.932 (20°); R. Fürstenau, 7.0, and

J. Joly, 7⁴. A. Winkelmann gave for the ratio $C_{100}/C_0=1.172$. H. F. Weber said that press. has very little influence on the sp. ht., but J. Joly found the sp. ht. rises with increasing press. more rapidly with carbon dioxide than with air. H. B. Dixon and F. W. Rixon found the sp. ht. of carbon dioxide at constant vol. to rise gradually with the temp., while variations of press. have but little influence. They obtained the following values for c_p reduced to a press. of 100 atm.:

	16°-115°	170°-118°	17-5°	21°-208°	21°-398°
c_p	0.2000	0.2004	0.2092	0.2884	0.3565

J. M. Crofts obtained 7.815 between 15° and 532°, 7.847 between 15° and 545°, 7.878 between 15° and 557°, and 7.909 between 15° and 570°. E. Mallard and H. le Chatelier represented their results by $C_v=6.5+0.00387 T$; H_2 le Chatelier, by $C_v=6.5+0.00387 T$; and $C_r=6.3+0.006 \theta -0.0_5 \theta^{1.82}$ K. Langen, by $C_v=6.7+0.0026 T$; M. Pier, by $C_v=6.800+0.0033 T -0.0595 T^2 +0.0.1 T^3$, at temp. between 0° and T° . The relation deduced by J. M. Crofts from G. N. Lewis and M. Randall's values is $C_v=5.0+0.0071 T -0.00000186 T^2$. F. G. Keyes and A. W. Kenney gave $c_p=0.1547+0.0001595 \theta -0.0.95 \theta^2$ cal. per gram at 15°. Other values were given by F. Kettel, W. A. D. Rudge, A. Willner, R. Threlfall, H. Valérius, R. Geipert, M. Trautz and B. Berneis, W. D. Womersley, R. T. Glazebrook, C. F. Jenkin and D. R. Pye, I. B. Zoch, M. Trautz and K. Hebbel, H. N. Mercer, etc.

C. F. Jenkin and D. R. Pye found the sp. ht. of the liquid carbon dioxide to be 0.551 at 0°, 0.523 at -20°, and 0.480 at -40°. C. Dieterici gave 0.50 at 0°; and F. G. Keyes and A. W. Kenney calculated 0.543 at 0° and -20°, and 0.544 at -40°. B. Schwalbe found the sp. ht. of the liquid to be $c_p=0.2164$. A. Berndt showed that at constant vol. the sp. hts. of liquid and vap. between -5° and 25° are the same. A. Eucken found the sp. ht. of solid carbon dioxide to be 1.08 at -253.6°, and 13.38 at -73.5°. C. F. Jenkin and D. N. Shorthose measured the total heat in liquid carbon dioxide. J. Kapp measured the sp. ht. of binary mixtures of carbon dioxide with oxygen, and argon; M. Berthelot and P. Vieille, of carbon dioxide with oxygen, and nitrogen; and J. M. Crofts, of carbon dioxide with electrolytic gas.

• The heat of formation of carbon dioxide has been discussed in connection with carbon. Determinations have been made by P. A. Favre and J. T. Silbermann,¹⁸ M. Berthelot, J. Thomsen, H. W. Schröder van der Kolk, etc. M. Berthelot gave (C, 20)=94 Cals. (CO, O)=66.81 to 68.28 Cals., and (CO, O, aq.)=72.69 Cals.; while J. Thomsen gave with amorphous carbon (C, 20)=96.96 Cals., (CO, O)=66.8 Cals., and (CO, O, aq.)=72.69 Cals., all at constant press. P. A. Favre and J. T. Silbermann gave for (C, 20) at constant press. with wood charcoal 96.98 Cals.; sugar charcoal, 96.53 Cals.; graphite, 93.36 Cals.; and the diamond, 93.24-94.55 Cals. M. Berthelot and P. Petit gave for diamond carbon (C, 20)=94.3 Cals., for graphite carbon, 94.8 Cals., and for amorphous carbon, 97.65 Cals., all at constant vol. V. Njegovan, R. C. Tolman and R. M. Badger calculated the entropy of carbon dioxide; and H. von Jüptner, the free energy, F , of the reaction $C+O_2=CO_2$; when p_1 and p_2 respectively denote the partial press. of oxygen and carbon dioxide, $F=98369.9-54.06 T+6.31 T \log T -0.00064 T^2 +4.56 T \log (p_1/p_2)$. W. Schütt, A. Eucken and co-workers, and K. Langen have discussed the internal energy, and the entropy of carbon dioxide. K. Langen calculated a heat-entropy diagram down to -50°. J. Thomsen found the heat of solution of a mol of carbon dioxide in 1500 mols. of water to be 5.880 Cals., and for the heat of neutralization of a mol of aq. carbonic acid with n mols of sodium hydroxide, $H_2CO_3aq. + nNaOH$:

	1	2	4
Heat of neutralization	110	202	204 Cals.

P. A. Favre and C. A. Valson gave for the dil. soln. $Na_2Oaq. + CO_2=Na_2CO_3aq. + 25.88$ Cals.; and N. N. Beketoff gave 75.28 Cals. for the same reaction. M. Berthelot

found for $(\frac{1}{2}\text{CO}_2\text{aq.}, \text{NH}_3\text{aq.}) = 5.35$ Cals. with a soln. of 1.25 grms. of carbon dioxide in a litre, or one eq. of the salt in 20 litres; and P. A. Favre and C. A. Valson gave 16.946 Cals. for the same reaction in dil. soln.

E. Mulder¹⁹ found that a small proportion of carbon dioxide enhances the luminosity of the flame of coal gas; but P. F. Frankland found that large proportions act in the opposite direction, for 60 per cent. of carbon dioxide completely destroys the luminosity of the flame of ethylene. A. Bunte, G. Frère, F. Clowes and co-workers have studied this subject. E. Rosetti gave for the combustion temp. of mixtures of one vol. of coal gas with n vols. of carbon dioxide,

n	0.5	0.67	1.0	1.5	2.0	3.0
Temp. of combustion	1190°	1170°	1100°	1020°	880°	780°

The index of refraction of carbon dioxide, without spectral resolution, has been measured by many observers. J. B. Biot and F. J. Arago²⁰ gave $\mu = 1.0004497$; P. L. Dulong, 1.0004495; J. Jamin, 1.0004500; W. Ramsay and M. W. Travers, 1.0004488. Other observations have been made by M. Croullebois, L. Boltzmann, C. and M. Guthbertson, F. Mohr, J. A. Wasastjerna, L. Bleckrode, J. Klemencic, etc. G. W. Walker obtained for Na-light, 1.000451. For light $\lambda = 535.2\mu\mu$, E. Ketteler found 1.0004507, and for $\lambda = 570.8\mu\mu$, 1.0004477; E. Mascart, for $\lambda = 480.0\mu\mu$, 1.0004587, and for $\lambda = 643.8\mu\mu$, 1.0004532; E. Perreau, for $\lambda = 467.7\mu\mu$, 1.0004550, and for $\lambda = 643.8\mu\mu$, 1.0004487; H. C. Rentschler, for $\lambda = 334.2\mu\mu$, 1.0004668, and for $\lambda = 577.1\mu\mu$, 1.0004487; J. Koch, for $\lambda = 435.9\mu\mu$, 1.0004563, and for $\lambda = 867.8\mu\mu$, 1.0004579; L. Stuckert, for $\lambda = 435.9\mu\mu$, 1.0004589, and for $\lambda = 670.8\mu\mu$, 1.0004466; and G. Gruschke, $\lambda = 447.2\mu\mu$, 1.0004568, and for $\lambda = 667.8\mu\mu$, 1.0004475. J. Kocfi found a marked anomaly in the ultra-red. M. Faraday, B. Schwalbe, and J. H. Niemann commented on the high refractivity of liquid carbon dioxide. L. Bleckrode found the index of refraction of liquid carbon dioxide is dependent on the temp., particularly in the vicinity of the critical temp., being 1.199 at 12.5°, 1.192 at 15.5°, 1.186 at 18.5°, and 1.173 at 24°. The crystals of the solid, said P. Villard and R. Jarry, have no action on polarized light. J. Chappuis and C. Rivière gave for the effect of press. p mm. up to 19 atm. at 21°, for the D -line, $\mu - 1 = 0.000540p(1 + 0.0076p + 0.0000050p^2)$. V. Posejpal also studied the effect of reduced press. on the index of refraction. It was found that the laws $(\mu - 1)/D = \text{constant}$, and $(\mu^2 - 1)/(\mu^2 + 2)D = \text{constant}$ hold good for press. up to 19 atm. P. Phillips gave $(\mu^2 + 2)/(\mu^2 - 1) = 6.581 + 0.1130D^2$. The dispersion has been measured by E. Mascart, M. Crouillebois, etc. The last-named found $\mu_o - \mu_s = 0.000014$; and $\mu_o - \mu_c = 0.000115$; and for $(\mu_o - \mu_c)/(\mu_s - 1) = 0.2214$. L. H. Sierstema and M. de Haas found the dispersion constants are independent of press. between 20 and 47 atm. H. Becquerel found the magnetic rotatory power for Na-light to be 12.18; and the ratio of the value for carbon dioxide to that of carbon disulphide to be 0.000302. T. M. Lowry found the index of refraction and sp. inductive capacity agree with the assumption that the molecule is not internally ionized. P. Glan found the optical properties of reflecting surfaces are not affected by carbon dioxide. J. W. Brühl gave for the molecular refraction, at 15.5°, 6.58 for the liquid, and 6.47 for the gas. The scattering of light in carbon dioxide has been discussed by M. Raman, and C. V. Raman, and K. S. Rao, A. S. Ganesan, K. R. Ramanathan, and, by Lord Rayleigh. The electromagnetic rotation, or Verdet's constant, ω , is, according to L. H. Sierstema, $\omega \times 10^6 = 2.682\lambda^{-1} + 0.6305\lambda^{-3}$ at 6.5° and at atm. press. when the wave-length, λ , is expressed in μ . The electromagnetic birefringence was studied by R. de Malleman, and N. Lyon.

The spark spectrum of carbon dioxide has been discussed in connection with carbon. Observations have been made by E. F. Barker,²¹ A. Wüllner, K. Wesendonck, H. Deslandres and L. d'Arambuja, G. Gehlhöff, W. H. Bair, W. W. Coblenz, F. Paschen, K. J. Angström, A. Hagenbach, F. Himstedt and H. von Dechen, W. H. Bair, etc. Carbon dioxide is a colourless gas, and it shows no visible absorption spectrum. In the ultra-red, there is a band with maximum intensity

corresponding with wave-length 4.76μ . The ultra-red emission spectrum of carbon dioxide at a press. of 0.6 mm.; by W. W. Coblentz, is illustrated in Fig. 50, which can be compared with Fig. 35, for carbon monoxide. He added that the "greater intensity of the band with carbon monoxide would make it appear as though the 4.75μ band were due to this gas." The atm. shows the same absorption bands; so does the flame in which carbon dioxide is a product of the combustion. J. Okubo showed that the nearer ultra-red spectrum of carbon dioxide comprises intense bands at 2.71μ and 2.77μ , and a somewhat weaker band at 2.61μ . There are a number of feebler bands with various maxima between 3.02μ and 2.29μ .

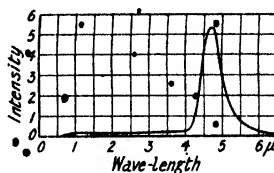

FIG. 50.—Ultra-red Emission Spectrum of Carbon Dioxide.

R. Schachenmeier made observations on the ultra-red spectrum of carbonates; and A. Balandin, and H. M. Randall, on the ultra-red spectrum of carbon dioxide. F. Paschen found that the effect of temp. on these bands is such that the maximum is displaced 4.270μ at 17° ; at 600° , 4.344μ ; at 1000° , 4.388μ ; and at 1900° , 4.403μ . There is also a band with a maximum 2.6μ in the ultra-red. H. Rubins and A. Aschkinass found a third absorption band with a maximum at 14.7μ . According to H. N. Kreusler, and V. Schumann, there is a faint absorption for ultra-violet rays more refrangible than 200μ . W. H. Miller showed that the gas is transparent to the actinic rays. C. Schäfer studied the effect of press. on the ultra-violet spectrum of carbon dioxide.

The absorption of heat rays has been investigated by K. J. Angström, W. Barrett, H. Heine, J. E. Keeler, E. Lecher, E. von Bahr, W. C. Röntgen, J. Tyndall, etc. The selective absorption of the heat rays represents the power possessed by carbon dioxide of hindering terrestrial radiations, and, by blanketing the earth, helps to avert excessive changes of temp. This question has been discussed by S. Arrhenius. He tried to picture the effect of a change in the proportion of carbon dioxide in the atm. on the surface temp. of the earth. The temp. of the earth's surface was assumed to be in equilibrium with that of the atm.; if by any increase in the amount of carbon dioxide the atm. retained more heat than before, it would radiate more heat to the surface of the earth. The surface temp. would then rise until equilibrium between the two occurred. The rise was assumed to be governed by the radiation law, and hence it was estimated that if the carbon dioxide is increased 2.5 to 3.0 times its present value, the temp. in the Arctic regions would rise 8° to 9° , and produce a climate as mild as that of the Eocene Period; a decrease of 0.55 to 0.62 times its present value would cause a fall of 4° to 5° and produce a glacial period. F. Reech, and C. F. Tolman support S. Arrhenius' views. E. Kayser, and C. G. Abbot and F. E. Fowle hold that the carbon dioxide in the atm. cannot absorb more than 16 per cent. of the terrestrial radiations; that variations in its amount are of small effect; and that the proportion of aq. vap. in the atm. is so large as to make the climatic significance negligible. The principal absorbent of terrestrial radiation is aq. vap.

R. K. McClung,²² and J. A. Crowther studied the ionization of carbon dioxide by hard and soft X-rays; P. Lenard, by cathode rays; T. H. Laby, R. A. Millikan and co-workers, and E. P. Metcalfe, by the α -rays from uranium, etc.; R. D. Kleeman, and T. H. Laby and G. W. C. Kaye, by γ -rays; and R. D. Kleeman, and R. J. Strutt, by Becquerel's rays. P. L. Kapitza measured the loss of energy by an α -particle passing through carbon dioxide; A. Lepape, the effect of carbon dioxide on the ionization current produced by α -rays; F. Hauer, the ionization by α -rays; and P. W. Burbidge, the absorption of X-rays. H. Baerwald, and A. Becker measured the absorption of cathode rays by carbon dioxide. H. Zickendraht studied the action of carbon dioxide on the fluorescence of sodium vap. The chemical effects of ultra-violet rays and radium radiations are indicated below. J. Elster and H. Geitel found that natural carbon dioxide from deep soils is radioactive.

G. Gehlhof²³ found that the cathode fall of potential when an electric discharge passes through carbon dioxide is not the sum of the separate values for the component atoms. He eliminated the effects due to the decomposing action of the discharge on the gas—*vide infra*. F. Narr, C. Richter, A. Becker, and C. E. and H. Guye studied the effect of carbon dioxide on the discharge from an influence machine. According to A. Becker, mercury in contact with carbon dioxide takes on a positive charge. E. Dycetret, L. Bleekrode, L. P. Cailletet, and B. Schwalbe found that when solid carbon dioxide is made by passing the gas into a bag or ebonite vessel both the receiver and the solid carbon dioxide are charged negatively, while the escaping gas is charged positively. Similarly, J. Joly found that a jet of gas from a copper bomb gives off electric sparks. G. Hausknecht said that the best electrical effects are obtained if the gas is quite free from air. M. Faraday, and K. Wesendonck said that it is doubtful if the gas alone, quite free from dust and moisture, would develop an electric charge by friction against metal. J. Elster and H. Geitel showed that the so-called electricity of flames is but a special case of the more general positive electrification of gases in contact with incandescent bodies (3, 26, 1). A. L. Hughes and A. A. Dixon gave 10 volts for the ionizing potential; C. A. Mackay, 14.3 volts; and K. T. Compton, 6.47–8.2 volts. H. E. Hurst studied the discharge potential of carbon dioxide; and C. E. Guye and co-workers worked with the gas under press.; C. E. Guye and R. Rudy also investigated the electromagnetic rotation of the gas; and J. Kunz, the press. in the corona discharge.

E. Becquerel²⁴ and E. Villari found the electrical resistance of carbon dioxide at a red heat to be 1.2 to 2.0 times that of air. G. Gore, L. P. Cailletet, and L. Bleekrode found liquid carbon dioxide to be a very poor conductor of electricity. The electrical conductivity of aq. soln. of carbon dioxide has been measured by E. Pfeiffer,²⁵ F. Kohlrausch, F. W. Knox, J. Walker and W. Cormack, etc. Aq. soln. of carbon dioxide have the properties of an acid—*vide infra*, action of water on carbon dioxide. It is therefore inferred that carbon dioxide is carbonic anhydride, and that the aq. soln. contains carbonic acid, H_2CO_3 . This acid has not been isolated because it so readily decomposes into water and gaseous carbon dioxide. When the aq. soln., coloured red by litmus, is boiled, the gas escapes, and the soln. acquires the neutral tint. According to the ionic theory, the acidity of the soln. is due to the presence of H^+ -ions derived from the ionization of carbonic acid: $\text{H}_2\text{CO}_3 \rightleftharpoons \text{H}^+ + \text{HCO}_3^-$. If v denotes the vol. of the soln. in litres containing a mol. of carbonic acid, and α be the proportion of acid ionized, then,

$$\frac{1-\alpha}{v} K_1 = \left(\frac{\alpha}{v} \right)^2; \text{ or } K_1 = \frac{\alpha^2}{(1-\alpha)v}$$

where K_1 represents the ionization constant in $\text{H}_2\text{CO}_3 \rightleftharpoons \text{H}^+ + \text{HCO}_3^-$. The subject has been discussed by A. Thiel, R. Strohecker, O. Haehnel, E. Wilke, and E. Pusch. J. Kendall measured the sp. conductivity of water in equilibrium with the carbon dioxide of the atm., and found the values 0.65×10^{-6} at 0° ; 0.75×10^{-6} at 18° ; and 0.80×10^{-6} at 25° , and, in agreement with J. Walker and W. Cormack, who said that carbon dioxide is the only substance in the atm. which confers conductivity on water; the purest distilled water of the laboratory is a sat. soln. of carbon dioxide under existing atm. conditions. F. W. Knox gave for the eq. conductivity, λ mhos, when a mol. of the acid, H_2CO_3 , is dissolved in v litres of water:

v	12.61	18.43	36.36	53.2	125	287	1099
λ	0.777	0.932	1.210	1.580	2.44	3.74	8.01
α	0.00210	0.00261	0.00367	0.00443	0.00684	0.01048	0.02244
$K_1 \times 10^7$	3.76	3.70	3.72	3.70	3.77	3.86	4.69

J. Walker and W. Cormack gave for the conductivity at infinite dilution 3.565, and calculated for the transport number of the hydrocarbonate ion, HCO_3^- , 40.5, and for the H^+ -ion, 316, from the conductivity of soln. of sodium hydrocarbonate; J. Kendall

ave 40.1 at 18°, 35 at 12.5°, and 25 at 0° for the HCO_3' -ion. Further observations give for the mean value of the ionization constant, $K_1=0.6,304$, or $K_1=3.04 \times 10^{-7}$ at 18°, according to J. Walker and W. Cormack; 3.34×10^{-7} at 12.5° and 3.75×10^{-7} at 18°, according to F. W. Knox; and 2.24×10^{-7} at 0°, 3.12×10^{-7} at 18°, and 3.50×10^{-7} at 25°, according to J. Kendall. The heat of ionization, $\text{H}_2\text{CO}_3\text{aq} \rightleftharpoons \text{H}^+ + \text{HCO}_3'$, given by J. Kendall was 0°-25°, -2.89 Cals.; 0°-18°, -2.91 Cals.; and 18°-25°, -2.83 Cals.; E. W. R. Pfeiffer gave -7.85 Cals. at 0°-12.5°; and F. W. Knox, -3.48 Cals. at 12.5°-18°. The ionization constant furnishes a ready means of comparing the strength of acids. Thus, at 18°:

	Acetic acid.	Carbonic acid.	Hydrosulphuric acid.	Cyanoacetic acid.	Boric acid.
K_1	1.8×10^{-5}	3.0×10^{-7}	9.0×10^{-8}	1.3×10^{-3}	5.8×10^{-10}

The percentage degrees of ionization, or the percentage amount of the acid ionized, are:

	CH_3COOH	H_2CO_3	H_2S	H_2BO_3	HCy
1% N-soln.	4.2	0.774	0.42	0.042	0.036
1% N-soln.	1.3	0.250	0.13	0.013	0.011

E. Pfeiffer, A. Lieben, J. Walker, etc., raised the question: *Is all the carbon dioxide in aq. soln. present as carbonic acid, or is part present as carbonic acid, and part present as free (or hydrated) carbon dioxide?* Let a denote the number of mols of unchanged carbon dioxide; b , the number of mols of non-ionized carbonic acid; and c , the number of mols of ionized carbonic acid. Then $a+b+c=1$. From the mass law, assuming that there is equilibrium between the free carbon dioxide in soln. and the carbonic acid, $a/v=kb/v$, where k is constant; hence, $b=a/k$. Substitute this value of b in the first equation, and $a/k=(1-a)/(1+k)$; or $b=(1-a)/(1+k)$. The equilibrium condition between ionized and non-ionized carbonic acid gives $(a/v)^2=K_1(b/v)$, and on substituting for b it follows that $a^2/(1-a)v=K_1/(1+k)$; but k is constant, and hence $a^2/(1-a)v=K$. The constancy of $a^2/(1-a)v$ thus furnishes no evidence as to the proportion of the carbon dioxide in aq. soln. present as carbonic acid, for the same relation is obtained whatever be the proportion.

The complete ionization of carbonic acid $\text{H}_2\text{CO}_3 \rightleftharpoons 2\text{H}^+ + \text{CO}_3''$ proceeds in two stages: $\text{H}_2\text{CO}_3 \rightleftharpoons \text{H}^+ + \text{HCO}_3'$, for which the ionization constant has just been shown to be $K_1=3 \times 10^{-7}$. The second stage is represented by $\text{HCO}_3' \rightleftharpoons \text{H}^+ + \text{CO}_3''$, or $[\text{H}][\text{CO}_3'']=[K_2][\text{HCO}_3']$. From J. Shields' observations on the hydrolysis of aq. soln. of sodium carbonate, and F. Kohlrausch and A. Heydweiller's value for the ionization constant of water, G. Bodländer calculated for the ionization constant of the second hydrogen ion $K_2=1.295 \times 10^{-14}$. Hence, K_1 is 23,000 times as great as K_2 . H. Menzel gave $K_2=6.2 \times 10^{-11}$ at 18°. By combining K_1 and K_2 , it follows that $\text{H}_2\text{CO}_3 + \text{CO}_3'' \rightleftharpoons 2\text{HCO}_3'$; and $[\text{HCO}_3']^2/[\text{H}_2\text{CO}_3][\text{CO}_3'']=K_1/K_2$, and $K_1/K_2=K_3$. H. N. McCoy found K_3 at 25° to be 5300. More exact values for the second ionization constant were determined by F. Auerbach and H. Pick, and E. B. R. Prideaux, and they find $K_2=6 \times 10^{-11}$. This subject has been discussed in connection with the hydrolysis of the carbonates and hydrocarbonates of the alkalies and alkaline earth metals (*q.v.*). A. Thiel and R. Strohecker represent the degree of ionization in terms of the carbonic acid actually formed rather than in terms of the amount of carbon dioxide dissolved. They estimate that in a 0.00812 molar soln. of this gas at 4°, only 0.67 per cent. is present as carbonic acid. Making allowance for this, the ionization constant of the first hydrogen-ion is 5×10^{-4} . L. J. Henderson has discussed the function of carbonic acid in preserving a neutral reaction in natural waters, and thus maintaining the characteristic chemical inactivity of water. O. Hähnle found that at a press. of 52 atm., and at 15°, the strength of carbonic acid is of the same order as formic acid. R. Strohecker made observations on this subject and found that the ionization constant is 44×10^{-5} , making the acid behave like a hydroxyformic acid; D. H. Jackson and J. R. McDermet, on the effect of the de-aeration of natural waters on the carbonate equilibrium; and I. N. Kugel-mass and A. T. Schohl, on the effect of the equilibrium on the physiology of bone calcification.

E. Wilke showed that the conductivity increases with time, possibly owing to disturbances produced by the current; the ionization constant thus appeared to increase from 3.07×10^{-7} to 4.5×10^{-7} in 3 hrs. Light acts similarly. The hydrogen ion conc. in the presence of alkali chlorides makes the carbonic acid appear like a strong acid, but the H-ion conc. increases more rapidly than the conc. of the acid. This is explained by assuming that the aq. soln. of carbon dioxide contains some orthocarbonic acid, H_4CO_4 , which, containing no ketonic oxygen, is a very weak acid; but in conc. salt soln. it is dehydrated, forming metacarbonic acid, $CO(OH)_2$, which behaves like a strong acid. E. P. Metcalfe studied the ionization of the gas.

According to E. Royer, and A. Coehn and S. Jahn, carbon dioxide is reduced electrolytically in aq. soln. of sodium hydrocarbonate, or better, potassium sulphate, but not in sodium carbonate or acid soln. With most cathodes, reduction takes place to a small extent; with a cathode of zinc, freshly coated with zinc from a potassium zinc cyanide bath, a 50 per cent. yield of formic acid is obtained. Repeated use of an amalgamated zinc cathode results at first in increased yields (up to 82 per cent.), but the cathode suddenly loses its activity. Amalgamated copper cathodes give constant yields (45 to 50 per cent.) on repeated use. After prolonged electrolysis of carbon dioxide in potassium sulphate soln., comparison of the acidity of the mixed cathode and anode soln. with the potassium permanganate titre shows the reduction to result in the formation of formic acid with little or no formaldehyde. Formic acid can also be obtained by electrolysis of an aq. soln. of carbon dioxide. R. Ehrenfeld electrolyzed, for 12 hrs. at ordinary temp., a soln. of commercial ammonium carbonate in one part of aq. ammonia, sp. gr. 0.910, and four parts of water contained in cells with the anode and cathode (platinum foil) separated by a porous partition. Ammonium formate was produced at the cathode when this consisted of amalgamated zinc and when a difference of potential of 5-10 volts and a current density of 0.01-0.08 amp. were employed. No formate could be detected (a) when iron, platinum, copper, lead, or nickel cathodes were used, (b) when the current density was less than 0.01 amp., nor (c) when the soln. was too dil., for example, one-fifth the above conc. Soln. of sodium carbonate or of carbonate and hydroxide do not yield formates under similar conditions. The formation is not due to the presence of carbamate in the commercial carbonate, but is attributed to the presence of $NH_4CO_3^-$ anions in the conc. soln. A. Bach has given a series of equations representing the different stages of electrolysis, but these are quite imaginary, and added W. Leib, lack any experimental foundation. The reduction of carbonic acid to carbon does not occur in any soln. of the carbonates, but F. Haber and S. Tolloczk found that if barium chloride be fused with 5-20 per cent. of barium carbonate, cooled, and electrolyzed at 550°-600° in a nickel crucible with a platinum cathode, carbon separates in a dendritic form. The anodic oxidation of carbonate soln. was found by E. J. Constan and A. von Hanssen, G. Hostelet, and F. Salzer to furnish percarbonic acid (*q.v.*). The electrolysis of carbonate soln. has been studied by P. Burkhard, H. Kolbe and R. Schmidt, C. Luckow, etc.

The dielectric constant of liquid carbon dioxide was found by F. Linde²⁶ to be 1.608 at -5°; 1.583 at 0°; 1.540 at 10°; and 1.526 at 15° for $\lambda = \infty$, and for the gas at 15° and 39 atm. press., 1.060; at 19.9 atm. press., 1.015; and at 9.4 atm. press., 1.009. Determinations were also made by L. Boltzmann, E. C. Fritts, J. Klemenic, and W. E. Ayrton and J. Perry. W. Herz found the dielectric constant at 10° to be 1.540; and at the critical temp. 1.27. H. Riegger gave 1.001392 at -73°. Carbon dioxide was first stated by M. Faraday,²⁷ F. Zantedeschi, and J. Plücker to be diamagnetic. R. Bernstein gave $+0.0002 \times 10^{-6}$ for the magnetic susceptibility in vol. units at atm. press. and 15°; G. Quincke gave at 16°, and 1 atm. press. $+0.017 \times 10^{-6}$ and at 10 atm. press., $+0.12 \times 10^{-6}$. T. Soné gave, -0.423×10^{-6} for the sp. magnetic susceptibility, and -0.1781×10^{-9} for the vol. susceptibility at 0° and 760 mm. A. Glaser investigated the diamagnetism of this gas. D. N. Mallik studied the magnetic rotation of the electric discharge in carbon dioxide. F. Weigt gave $(0.1420 \pm 0.0017) \times 10^{-18}$ for the electrical moment

of carbon dioxide. W. M. Young measured the ionic mobility in the corona discharge; and H. A. Erikson, and G. C. Grindley and A. M. Tyndall, the mobility of ions in carbon dioxide.

§ 35. The Solubility of Carbon Dioxide

J. Dalton,¹ and W. Henry noted that water dissolves approximately its own vol. of carbon dioxide. F. M. Buamert also observed that at 3° 2' and 760 mm. press., one vol. of water dissolves 1.5184 vol. of the gas, and at 19° 6', 0.8545 vol. W. B. and R. E. Rogers, R. Bunsen, G. Geffcken, E. Bauer, E. Fernet, G. Just, F. Exner, J. H. Coste, K. Angström, E. Wiedemann, W. Kunerth, S. Gniewasz and A. Walfisz, N. de Khanikoff and V. Louguine, W. Sander, C. Bohr and J. Bock, L. W. Winkler, P. Rischbieth, etc., have made observations on the solubility of carbon dioxide in water. C. Bohr and J. Bock gave for the solubility, *S*, expressed in grams of carbon dioxide in 100 grms. of water, and the absorption coeff., β :

	0°	5°	10°	15°	20°	25°	30°	40°	50°	60°
<i>S</i>	1.713	1.424	1.194	1.019	0.878	0.759	0.665	0.530	0.436	0.359
<i>S</i>	0.335	0.277	0.231	0.197	0.169	0.145	0.126	0.097	0.076	0.058

thus showing that at a fixed press., the vol. of gas absorbed by a liquid decreases with rise of temperature. F. Henrich represented R. Bunsen's results at 0° by the formula: Absorption coeff., $\beta = 1.7326 - 0.066724\theta + 0.0012394\theta^2$; and A. Naccari and J. Pagliani gave $\beta = 1.5062 - 0.036511\theta + 0.0002917\theta^2$. A. Hantzsch and A. Vagt measured the distribution of carbon dioxide between air and water at different temp. J. Dalton, and W. Henry showed that the amount of gas dissolved at a given temp. is roughly proportional to the pressure as indicated by Henry's law (I. 10, 4). H. V. Regnault showed that the relation is not strictly followed; and N. de Khanikoff and V. Louguinine found that the amount of carbon dioxide dissolved is rather greater than corresponds with the proportional rule, and that the difference increased as the press. was augmented. S. von Wroblewsky observed that the coeff. of absorption increases less rapidly than the press. and tends towards a limiting value. Thus, if S denotes the vol. of gas absorbed by one c.c. of water, he found that at the press. p atm.

p .	1	5	10	15	20	25	30
0°	$\{S$. . . 1.797	8.65	16.03	21.95	26.65	30.55	33.74
	$\{S/p$. . . 1.797	1.730	1.603	1.463	1.332	1.222	1.124
12.43°	$\{S$. . . 1.086	5.15	9.65	13.63	17.11	20.31	23.25
	$\{S/p$. . . 1.086	1.030	1.965	0.909	0.855	0.812	0.775

W. Sander measured the solubility of carbon dioxide in water between 20° and 100° , and between 20 and 170 kgrms. per sq. cm. press. and found that at low temp. the results deviate from Henry's law, but the accord is closer when the vol. of gas absorbed is referred to the vol. of the soln. and not that of the solvent. The law is more nearly followed at higher temp., and at 100° , the solubility is proportional to the press. thus corresponding with Henry's law. This is shown by the following selection, where C represents the vol. of gas (reduced to one kgrm. per sq. cm.) absorbed by one c.c. of the soln., and p , the press. in kgrms. per sq. cm.:

20°	$\{p$. . . 25	30	40	50	55	
	$\{C$. . . 17.77	19.77	21.52	23.09	24.75	
35°	$\{p$. . . 30	40	50	60	70	80
	$\{C$. . . 13.57	20.60	24.64	22.50	27.62	32.85
60°	$\{p$. . . 40	50	60	80	100	120
	$\{C$. . . 9.80	13.72	15.28	22.67	27.85	33.90
100°	$\{p$. . . 70	90	110	130	150	170
	$\{C$. . . 6.40	10.85	16.31	16.89	17.49	22.78

The data are plotted in Fig. 51. W. P. Heath, C. G. Anthony, and W. A. Riley have calculated tables of the solubilities of carbon dioxide in water at different temp.

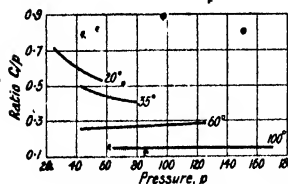

FIG. 51.—Effect of Temperature and Pressure on the Solubility of Carbon Dioxide in Water.

and press. O. Haehnel also measured the effect of press. on the solubility of carbon dioxide. C. Zerbe tried unsuccessfully to remove 10 per cent. of carbon dioxide from a mixture containing carbon monoxide and hydrogen by scrubbing the gas with water at 150 atm. press. Excessive amounts of other gases were dissolved.

According to S. von Wroblewsky, there is a close relation between the solubility of carbon dioxide in water and the surface tension, σ , of the soln. at press. from 1 to 30 atm. The product of the surface tension

and the press., p , is proportional to the coeff. of saturation, S , so that $\sigma p = KS$, where K is a coeff. which increases with temp. The variation in the surface-tension is independent of the press., and depends only on the amount of gas dissolved in the superficial layer of the liquid. The solubility of carbon dioxide in water increases less rapidly than the press., and tends towards a limit which is apparently reached when the carbon dioxide liquefies, since the liquid does

not mix with water. The diminution of the surface-tension also decreases as the press. rises, and tends towards a limit which, at 0° , is reached when the press. is sufficient to liquefy the carbon dioxide. At this point the surface-tension of the water is reduced by one-half. W. A. Patrick represented the solubilities of a number of gases in water by the formula $S = K(\sigma p/p_0)^{n-1}$, where S is the vol. of liquefied gas dissolved per gram of water (i.e. the weight of the gas dissolved per gram divided by the sp. gr. of the liquefied gas at that temp.); p_0 is the vapour press., and σ the surface tension of the liquefied gas at that temp. of measurement; p is the equilibrium gas press.; and K and n are specific constants. B. S. Neuhausen found the results satisfactory when $K = 0.006$, and $n - 1 = 0.33$. M. Thilorier, J. K. Mitchell, L. P. Cailletet, and B. Schwalbe found that liquid and solid carbon dioxide do not mix readily with water. A little liquid carbon dioxide dissolves when it is shaken with water, and the excess of the former floats on the surface of the water. According to H. Landolt, solid carbon dioxide sinks in water although a little may be floated by the rising of bubbles of gas without being wetted by the water.

K. Angström found the *specific gravity* of water after it has absorbed an equal vol. of carbon dioxide at 0° and 760 mm. is 1.00054, and unit vol. becomes 1.00125. E. L. Nichols and co-workers found that the temp. of *maximum density*, and the *freezing point* of water are lowered by dissolved carbon dioxide. They found the following expansions to attend the absorption of carbon dioxide:

	2°	6°	8°	12°	16°	18°	22°	32°
Expansion	0.002144	0.001726	0.001670	0.001540	0.001378	0.001280	0.001210	0.001010

showing that the expansion is directly proportional to the amount of gas absorbed. G. A. Hagemann made an estimate of the energy which attends the association of carbon dioxide and water. A. Blümcke said that the compressed carbon dioxide in water behaves as if it were a liquid, not a gas.

The rate of evolution of a gas from a liquid, expressed in terms of the number of c.c. of gas at 0° and 760 mm., given off per minute per sq. cm. of surface, was called by C. Bohr, the *evasion coefficient*, and the converse process, the rate of absorption, was called the *invasion coefficient*. J. Hurtur measured the rate of absorption of carbon dioxide by calcium oxide. J. J. Hood studied the absorption of carbon dioxide by aq. soln. of potassium hydroxide; P. Riou, by soln. of potassium and sodium carbonates, and ammoniacal soln.; J. Meyer, and W. A. Roth, the rates of evolution and absorption of carbon dioxide by water. W. F. Knox found that the rate of evolution of carbon dioxide from its aq. soln. follows approximately a logarithmic rule, and E. P. Perman made some observations on this subject. T. Carlson found the rate of absorption of carbon dioxide by water at rest is dependent on the rate of diffusion of the gas into the bulk of the liquid from the sat. surface, so that if C be the conc. of the gas dissolved at the time t , and S the conc. of the sat. soln., the velocity of absorption, dC/dt , is

$$\frac{dC}{dt} = K(S - C); \text{ or } \frac{1}{t} \log \frac{1}{S - C} = K$$

where K is a constant dependent on the diffusion coeff., and the thickness a of the saturation layer; if the liquid be stirred with a paddle making n revolutions per minute, then $K = K'n^3 Da$, where K' is a constant dependent on the apparatus employed. A. Findlay and G. King found that the rate of evolution of carbon dioxide from soln. of that gas is fastest with soln. having the smallest surface tension; but A. Findlay and O. R. Howell found that in the presence of colloids the relationship is in the converse direction, and hence they inferred that "it is not the surface tension of the soln. which determines the rate of escape of a gas, but rather the internal press. of the liquid." A. Sieverts and A. Fritzsche, E. M. Baker, R. V. Williamson and J. H. Mathews, and P. G. Ledig and E. R. Weaver measured the rate of absorption of carbon dioxide by water and alkaline soln.

In general, supersaturation occurs more readily in gas soln. than in any other case. Supersaturation persists for a long time in rigorously clean glass vessels. L. Pratesi found that certain mineral waters—e.g. that from Contursi in Salerns—contain a larger amount of carbon dioxide in soln. than corresponds with the solubility of the gas. Ordinary seltzer water drawn from a siphon, and allowed to stand half an hour, contains 1.901 vols. of carbon dioxide under conditions where the solubility of the gas would be represented by 1.289 vols. Hence a sat. aq. soln. of carbon dioxide under press., left for some time under ordinary press., contains a larger quantity of gas than water simply sat. with the gas at ordinary press. Aq. soln. of carbon dioxide are very readily supersaturated. J. Melschl studied the supersaturation of alcohol and water by carbon dioxide.

Some observations on the subject were made at the beginning of the nineteenth century by J. J. Winter, and H. C. Oersted; and there has been some discussion by D. Gernez, G. van der Mensbrugghe, C. F. Hengici, C. F. Schönbein, H. Schröder, C. Tomlinson, R. Fricke and C. Rohmann, F. B. Kenrick and co-workers, Lord Rayleigh, etc., on the formation of gas bubbles in supersaturated soln. of gas.

W. Ostwald has shown that the supersaturation of a liquid by gas occurs if the pressure be reduced and gas nuclei are absent. The study of surface-energy (1. 13. 22) shows that supersaturation must take place if gas nuclei are absent. Since the surface tension of a liquid tends to diminish the surface, there must be a greater press. in the interior of a spherical bubble than at a plane surface under the same circumstances, and the theory of capillarity gives for this the equation $p = 2\gamma/r$, where p is the press., γ the surface tension, and r the radius of the sphere. If, therefore, a bubble of gas is formed spontaneously, it will be under a far greater press. than corresponds to saturation under the given conditions. It appears from this that a bubble could not be formed spontaneously at all. For, as at the first instant the bubble must be infinitely small, the press., according to the equation, must be infinitely great. The spontaneous formation of bubbles shows that the assumption that the properties of a liquid remain the same up to infinitely small dimensions, is incorrect. If the limit for the ordinary properties of liquids is put at 10^{-8} cm., the press. in a bubble of this radius in water at room temp. is calculated to be 15,000 atm. Apparently nothing like this degree of supersaturation is necessary to cause spontaneous evolution of gas.

To remove the supersaturation, the soln. can be brought into an atm. of the gas at a reduced press. or of another gas in which the partial press. of the dissolved gas is zero. The addition of porous powders which enclose large surfaces with adsorbed air acts similarly; violent shaking acts by spreading numerous air-bubbles through the liquid; and boiling the solvent acts by introducing bubbles of vapour throughout the liquid. Each bubble of gas acts as a nucleus facilitating the formation of a new phase; the action of each bubble is local, and when it has risen to the surface and escaped from the liquid, no more bubbles are spontaneously evolved. Hence, a supersaturated soln. of a gas expels the nuclei which are necessary to relieve supersaturation. Many aerated beverages are charged with carbon dioxide at about 4 atm. press., and when the first effervescence which attends the pouring is over, small bubbles develop at the places where the glass has been scratched and some air has been imprisoned. This is illustrated by the fact that if a "sparkling" liquid be poured into a wetted glass vessel, it appears "flat"; and the introduction of powdered sugar or a roughened surface restarts the evolution of gas.

W. Hempel and J. Seidel² noticed that carbon dioxide unites with water when under 43 atm. press., forming a compound which melts at 8°, and decomposes at -2° under atm. press. A few hydrates of carbon dioxide have been reported. R. Bunsen computed that the water and carbon dioxide adsorbed by moist glass-wool are related as $\text{CO}_2 : \text{H}_2\text{O} = 2 : 1$, and he suggested that under the influence of the capillary press., it is possible that hemihydrated carbon dioxide is formed: $\text{CO}_2 \cdot \frac{1}{2}\text{H}_2\text{O}$. According to S. von Wroblewsky, when an excess of carbon dioxide at 0° and 45 atm. press. is allowed to stand in contact with water, some of the gas liquefies, and two liquids appear—the lower liquid is water with more or less carbon dioxide in soln., and the upper liquid is carbon dioxide. If the press. be slowly released, the liquid carbon dioxide slowly vaporizes, but if rapidly decreased to 12.3 atm.,

a solid collects on the walls of the containing vessel. He infers that this solid is a hydrate which decomposes at press. less than

Pressure	12.3	16.7	17.9	21.8	23.3	26.1 atm.
Temperature	0°	2.7°	3.6°	5.3°	6.3°	6.8°

S. von Wroblewsky's, and W. Hempel and J. Seidel's analyses correspond with *octohydrated carbon dioxide*, $\text{CO}_2 \cdot 8\text{H}_2\text{O}$; but P. Villard's analyses correspond with *hexahydrated carbon dioxide*, $\text{CO}_2 \cdot 6\text{H}_2\text{O}$. P. Villard said that combination occurs under simple press., and the hydrate does not decompose below 0° under ordinary press. except in the presence of liquid water. M. Ballo made some observations on this subject. W. Hempel and J. Seidel also sealed a weighed quantity of water and solid carbon dioxide in a tube; at ordinary temp., the liquid formed two layers, the water underneath; on cooling the tube slowly, crystals formed; these began to melt at about 8°. The tube was then cooled to -79°, opened, furnished with a delivery tube dipping under mercury, and then allowed to rise in temperature; carbon dioxide was evolved furiously at first, but ceased to come off at -25°; at -2°, the evolution of gas again commenced, and the volume that came off between this temperature and 20° corresponded with the octohydrate, or *enueahydrated carbon dioxide*, $\text{CO}_2 \cdot 9\text{H}_2\text{O}$. P. Villard found that the crystals are hexagonal prisms, and when deposited from aq. soln., the crystals are acicular like those of ammonium chloride. S. von Wroblewsky said that the density of the hydrate is greater than that of water sat. with carbon dioxide. P. Villard gave 14.9 Cals. for the heat of formation of the hexahydrate, and he gave for the dissociation press., *p*,

<i>p</i>	-6°	0°	0.48°	2.7°	3.6°	5.3°	6.1°	6.8°	10.0°
	6.5	12.2	12.7	16.7	17.9	21.8	23.3	26.1	44.3 atm.

The fact that the relative proportion of water and carbon dioxide has no influence on the dissociation press. is taken to indicate that only one hydrate is formed. The subject was discussed by H. W. B. Roozeboom. P. Villard's crystals had no action on polarized light.

When carbon dioxide dissolves in water it furnishes a soln. with the properties of a weak acid. How does the formation of carbonic acid affect the application of the law of partial press. (1. 10, 5)? The rule that at any given temp. the amount of, say, carbon dioxide absorbed from the atm. by water, is the product of the amount dissolved under 760 mm. press. of carbon dioxide alone, by the partial press. of that gas in air, holds good in spite of the chemical reaction $\text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{H}_2\text{CO}_3$. Let the chemical symbols in brackets denote the conc. of the compound, then, from the law of mass action: $[\text{CO}_2][\text{H}_2\text{O}] = K_1[\text{H}_2\text{CO}_3]$, but the conc. of the water is so greatly in excess that its conc. can also be regarded as a constant, K_2 , and if $K_1/K_2 = K$, then $[\text{CO}_2] = K[\text{H}_2\text{CO}_3]$, meaning that the conc. of the carbonic acid, H_2CO_3 , is proportional to the amount of carbon dioxide dissolved, and this in turn is proportional to the partial press. of the gas.

From the law of partial press., and C. Bohr and J. Bock's data,³ it follows that a litre of water should dissolve from air containing 0.03 per cent. of carbon dioxide:

	0°	5°	10°	15°	20°	25°	30°
Carbon dioxide	0.514	0.427	0.358	0.306	0.264	0.228	0.199 c.c.

Natural waters, however, usually contain alkali or alkaline earth carbonates in soln. as hydrocarbonates, which give up their carbon dioxide on boiling. F. M. Baumert's and E. M. Péligot's analyses of the gases in rain-water show respectively 1.8 and 2.4 per cent. of carbon dioxide at ordinary temp. The data correspond with those required for air with 0.03 per cent. of carbon dioxide. R. Bunsen found in the gases of rain-water 2.92 per cent. carbon dioxide at 0°; 2.68 at 5°; 2.46 at 10°; 2.26 at 15°; and 2.14 at 20°. H. McLeod's and E. Frankland's analyses gave 6.2 per cent. of carbon dioxide, and corresponded with an atm. with 0.1 per cent. of that gas. E. Frankland's analyses of the gases from a Cumberland mountain stream gave

0.281 per cent. of carbon dioxide, and those from the water of the Thames gave 4.021 per cent., and E. Reicherts' analysis of the Jena water supply gave 2.47 per cent. of carbon dioxide. The variable proportions here correspond with the presence of variable amounts of hydrocarbonates in these natural waters. C. J. J. Fox found between 1 and 7 parts of carbon dioxide per 10,000 parts of sea-water; and that the total alkalinity varies, but for the open ocean it is eq. to about 40 *mgms.* of OH per litre at 12°. The ratio of total carbon dioxide to total OH is linear, and there are no CO_3^{--} -ions; all the combined carbon dioxide is in the form of HCO_3^- -ions.

C. G. C. Bischof estimated that 60 per cent. of the total solids in waters of the principal rivers of Europe is dissolved as calcium hydrocarbonate and delivered into the sea. The ocean is not sat. with calcium hydrocarbonate; this, according to C. F. Tolman, is shown by the fact that (i) W. Dittmar found that except in one or two cases, lime was not deposited from the hundreds of samples of sea-water collected by the *Challenger*, after they had been kept for many years; (ii) B. Willis found that sea-shells from the bottom of the Pacific were much corroded; pteropod shells and foraminifera tests are slowly dissolved as they sink; and pteropod shells are not found below 1500 fathoms, and globigerina ooze, not below 2800 fathoms; (iii) J. Thoulet found that sea-water will dissolve calcium carbonate from shells, corals, etc.; and (iv) J. Usiglio observed no precipitation occurred in the evaporation of sea-water until the sp. gr. rose from 1.02 to 1.0503, and the deposit then consisted largely of calcium carbonate and ferric oxide. The analyses of O. Jacobsen, A. Hamberg, H. Tornøe, W. Dittmar, F. Natterer, and J. Y. Buchanan show that the amount of carbon dioxide in sea-water is not usually sufficient to transform all the normal calcium carbonate into hydrocarbonate; and that the largest part of the so-called free carbon dioxide is present as hydrocarbonate in equilibrium with the carbon dioxide in soln. and in the air. According to J. Johnston and E. D. Williamson, the warm surface layers of the ocean are practically sat. with carbonates, which are subject to precipitation not only by fluctuations of temp. but also by fluctuations in the proportion of carbon dioxide in the atm. above. W. Dittmar found that between 18° and 21°, the dissociation press. of the hydrocarbonates in sea-water is 0.0005 atm., and at temp. near 0° there is no dissociation at all. Since the partial press. of the carbon dioxide in the atm. is about 0.0003 atm., it follows that the warmer portions of the ocean are constantly supplying carbon dioxide to the atm., and the colder portions are constantly removing that gas. C. F. Tolman added:

The increase in the ocean's capacity for carbon dioxide at low temp. and the invasion of polar waters towards the equator both tend to rob the atm. of carbon dioxide, and this is unaffected by any diminishing partial press. of that gas. In the temperate waters, the effects of increasing cold and decreasing partial press. seem to be fairly evenly balanced, with a possible advantage for the diminishing partial press., against which must be reckoned a decrease in the amount of these waters. In the equatorial waters, the effect of the decreasing press. exceeds that of falling temp., counterbalanced by a large decrease in the amount of these waters.

C. J. J. Fox concluded that for the open ocean it requires 17.6 times as much carbon dioxide to raise the partial press. of that gas as it does for the same vol. of air; or, if a quantity of carbon dioxide is poured into the air, as, for example, by volcanic action, two-thirds will eventually be absorbed by the sea. The final equilibrium will not be attained, however, until either the insoluble carbonates on the sea-bottom or the carbon dioxide in the air have completely gone into soln. in the form of HCO_3^- . The conc. of the free ions, HCO_3^- and H^+ , for ocean-water are calculated to be respectively 2.24×10^{-3} and 1.6×10^{-6} to 2.6×10^{-6} gram-eq. per litre; thus sea-water has a slightly higher conc. of H^+ -ions than distilled water. S. Palitzsch found great constancy in the conc. of the hydrogen ions in sea-water (excluding the Black Sea); the extreme variations were 0.011N to 0.0345N; and the conc. of the hydroxyl ions, 0.02N to 0.055N. This is a sufficient excess to be

termed faint alkalinity. The ratio between hydrocarbonates and carbonic acid in sea-water is estimated by L. J. Henderson to be between 50 : 1 and 1000 : 1.

H. M. Noad⁴ observed that no considerable amount of carbon dioxide is absorbed by conc. sulphuric acid. W. B. and R. E. Rogers found one vol. of conc. sulphuric acid absorbs 0.76 vol. of carbon dioxide at 16°; and one vol. of fuming sulphuric acid absorbs 1.25 vol. of the gas. They added that the carbon dioxide is not completely expelled by heating the acid soln. to 100°. The solubilities of carbon dioxide in aq. soln. of sulphuric acid at 15°–25° have been determined by A. Christoff, C. Bohr, J. Maas, and G. Geffcken; the last-named found for unit vol. of soln. with 24.52 grms. of H₂SO₄ per litre, 1.018 vol. of gas were dissolved at 15° and 0.794 vol. at 25°; and with 196.15 grms. of acid per litre, 0.828 vol. of gas at 15°, and 0.667 vol. at 25°. The first-named found that at 20° the solubility fell from 0.9674 for water to 0.6521 with 35.82 per cent. acid, and then rose to 0.7191 for 61.62 per cent. acid, and to 0.9924 for 95.6 per cent. acid. A. Hantzsch and A. Vagel measured the distribution of carbon dioxide between air and dil. sulphuric acid at different temp. G. Geffcken found for hydrochloric acid with 18.23 and 72.92 grms. of acid per litre, the respective solubilities 1.043 and 1.000 at 15°, and 0.806 and 0.795 at 25°; for nitric acid with 31.52 and 126.10 grms. of acid per litre, the respective solubilities 1.078 and 1.100 at 15°, and 0.840 and 0.877 at 25°. F. L. Usher found a ½N-soln. of acetic acid had an absorption coeff. of 0.869. G. Just found that one c.c. of glacial acetic acid dissolved 5.614 c.c. of gas at 15°; 5.129 c.c. at 20°; and 4.679 c.c. at 25°; acetic anhydride, 6.128 (15°), 5.720 (20°), and 5.206 (25°); propionic acid, 4.787 (15°), 4.407 (20°), and 4.078 (25°); butyric acid, 4.084 (15°), 3.767 (20°), and 3.478 (25°). W. Kunerth measured the solubility in acetic acid. J. Setschenoff found for soln. with 12 and 595 grms. of citric acid per litre, the respective solubilities 1.007 and 0.719 c.c. of gas at 0° and 760 mm. per c.c. of soln.

J. Setschenoff found that the solubility of carbon dioxide in dil. salt soln. follows the same law as if the salt be absent provided there be no chemical reactions between the gas, the salt, and the solvent; but with increasing proportions of salt, the solubility of the gas decreases, presumably because the attractive power between the solvent and the gas is partially satisfied by the salt mol. He divides the salts into two groups with respect to their behaviour towards carbon dioxide. In the one group, the salts are not affected by the gas—e.g. sodium chloride; in the other group the salts react with the gas—e.g. sodium carbonate, phosphate, the borates, citrates, and oxalates. In the first group, the solubility of the gas decreases with increasing conc. of the soln., and in the other group the solubility of the gas increases with increasing conc. of the soln.

J. J. Mackenzie, A. Findlay and B. Shen, and J. Setschenoff measured the solubility of the gas in soln. of ammonium chloride. The last-named gave for soln. with 1 and 258 grms. of salt per litre solubilities respectively 1.005 and 0.770 c.c. at n.p.θ. per c.c. of sat. soln. at 15.2°; for soln. with 16.72 and 501.5 grms. of lithium chloride per litre he obtained the respective solubilities 1.035 and 0.120 c.c. of the gas calculated at n.p.θ. per c.c. of sat. soln. at 15.2°—other determinations were made by A. Christoff. The effect of sodium chloride on the solubility of carbon dioxide has been investigated by H. Müller, E. Fernet, J. J. Mackenzie, A. Christoff, and J. Setschenoff. The last-named found that with a soln. containing 12.9 and 192 grms. of the salt per litre, the respective solubilities were 0.978 and 0.468 c.c. of gas at n.p.θ. The effect of potassium chloride has been measured by J. J. Mackenzie, G. Geffcken, A. Findlay, and H. J. M. Creighton, and A. Findlay and B. Shen. The last-named found for soln. with 18.4 and 74.6 grms. of salt per litre, the respective solubilities 0.792 and 0.701 c.c. per c.c. of sat. soln. at 25°. The effect of rubidium chloride was measured by G. Geffcken, who found that with soln. containing 60.47 and 120.95 grms. of salt per litre the respective solubilities were 0.989 and 0.921 c.c. per c.c. of sat. soln. at 15°, and 0.769 and 0.788 at 25°; and with soln. containing 84.17 grms. of caesium chloride per litre the respective solubilities were 1.006 and 0.781 c.c. per c.c. of sat. soln. at 15° and 25°. J. J. Mackenzie found for soln. with 4.365 and 15.793 per cent. of calcium chloride the respective absorption coeff. 0.942 and 0.632 at 8°; 0.759 and 0.420 at 16.5°; 0.673 and 0.471 at 28°; and 0.596 and 0.400 at 30°; similarly, for soln. with 9.511 and 31.194 per cent. of strontium chloride, the absorption coeff. 0.779 and 0.285 at 8°; 0.663 and 0.245 at 16.5°; 0.581 and 0.247 at 22°; and 0.508 and 0.223 at 30°; and for soln. with 7.316 and 25.215 per cent. of barium chloride, the respective absorption coeff. 0.969 and 0.495 at 8°; 0.744

and 0.618 at 16.5°; 0.689 and 0.383 at 22°; and 0.568 and 0.315 at 30°. J. Setschenoff found that soln. containing 115.1 and 690.4 grms. of sodium bromide per litre, dissolved respectively 0.775 and 0.221 c.c. of gas at n.p.θ. per c.c. of soln. at 15.2°. The effect of potassium bromide was investigated by A. Christoff, G. Geffcken, and J. Setschenoff. The latter found for soln. with 83.9 and 503.1 grms. of the salt per litre the respective solubilities 0.908 and 0.579 c.c. of gas at n.p.θ. per c.c. of soln. at 15.2°; and for soln. with 310.1 and 957.3 grms. of potassium iodide per litre, the respective solubilities 0.777 and 0.506 c.c. of gas at n.p.θ. per c.c. of soln. at 15.2°. Measurements were also made by G. Geffcken, and A. Christoff. J. Setschenoff found for soln. with 233.3 and 699.6 grms. of sodium chlorate per litre the respective solubilities 0.625 and 0.527 c.c. of gas at n.p.θ. per c.c. of soln. at 15.2°; and for soln. with 326 and 978 grms. of potassium thiocyanate per litre, the respective solubilities 0.691 and 0.387 c.c. of gas at n.p.θ. per c.c. of soln. at 15.2°.

The effect of ammonium sulphate was measured by A. Christoff, and J. Setschenoff; the latter found that with soln. containing 72.2 and 144.4 grms. of the salt per litre, the respective solubilities were 0.712 and 0.575 c.c. of gas at n.p.θ. per c.c. of soln. at 15.2°; and soln. with 14.2 and 284.4 grms. of sodium sulphate per litre dissolved respectively 0.950 and 0.234 c.c. of gas at n.p.θ. per c.c. of soln. at 15.2°. A. Christoff found that 75 c.c. of 0.66N- and N-soln. of potassium sulphate dissolved respectively 0.1140 and 0.1002 grms. of carbon dioxide at 15.5° and 760 mm.; 75 c.c. of 0.66N- and 2N-soln. of potassium hydrosulphate dissolved respectively 0.1020 and 0.1000 grm. of gas at 15.5° and 760 mm.; and 75 c.c. of 2N-soln. of cupric sulphate dissolved 0.0751 grm. of gas. J. Y. Buchanan tested the action of carbon dioxide on soln. of calcium sulphate. J. Setschenoff, J. Y. Buchanan, and A. Christoff measured the effect of magnesium sulphate and of zinc sulphate. The former observed that soln. with 26.5 and 318 grms. of magnesium sulphate per litre dissolved respectively 0.901 and 0.188 c.c. of gas at n.p.θ. per c.c. of soln. at 15.2°; and soln. with 38.3 and 460 grms. of zinc sulphate per litre dissolved respectively 0.903 and 0.209 c.c. of gas at n.p.θ. per c.c. of soln. at 15.2°. A. Findlay and B. Shen found that at 25°, soln. with 95.1 and 224.7 grms. of hexahydrated ammonium ferrous sulphate per litre dissolved respectively 0.641 and 0.460 c.c. of gas per c.c. of soln. A. Christoff found that at 15.5°, 75 c.c. of a N-soln. of ammonium ferric sulphate dissolved 0.0991 grm. of gas; and 75 c.c. of a N-soln. of potassium aluminium sulphate dissolved 0.1054 grm. of gas.

J. Setschenoff found that soln. with 2.8 and 810.4 grms. of ammonium nitrate per litre dissolved respectively 1.013 and 0.612 c.c. of gas at n.p.θ. per c.c. of soln. at 15.2°; and soln. with 89.3 and 625.2 grms. of sodium nitrate per litre dissolved respectively 0.835 and 0.244 c.c. of gas at n.p.θ. per c.c. of soln. at 15.2°. A. Christoff, G. Geffcken, and J. Setschenoff measured the effect of potassium nitrate; the last-named found that soln. with 58.8 and 235.1 grms. of the salt per litre dissolved respectively 0.959 and 0.781 c.c. of gas at n.p.θ. per c.c. of soln. at 15.2°; he also found that a soln. with 41 grms. of calcium nitrate per litre, and one with 62.7 grms. of barium nitrate per litre dissolved respectively 0.923 and 0.922 c.c. of gas at n.p.θ. per c.c. of soln. at 15.2°. A. Christoff found that at 15.5°, 75 c.c. of a N-soln. of normal dodecahydrated sodium orthophosphate dissolved 0.5828 grm. of gas. J. S. F. Pagenstecher, J. J. Berzelius, J. von Liebig, J. Setschenoff, R. L. Marchand, and R. Heidenhain and L. Meyer have studied the action of carbon dioxide on soln. of sodium hydrophosphate. A. Christoff found that at 15.5° the solubility of carbon dioxide, in c.c. of gas per c.c. of a soln. of normal decahydrated sodium pyrophosphate, is 0.8463 grm.; sodium metaphosphate, 0.0700 grm.; N-soln. of potassium dihydrophosphate, 0.0860; $\frac{1}{2}$ N-soln. of potassium hydrophosphate, 0.4900 grm.; N-soln. of potassium metaphosphate, 0.1237; N-soln. of potassium dihydroarsenate, 0.0812 grm.; $\frac{1}{2}$ N-soln. of potassium hydroarsenate, 0.1110; $\frac{1}{2}$ N-soln. of ammonium hydrometaborate, $(\text{NH}_4)\text{H}(\text{BO}_2)_2$, 0.7672 grm.; $\frac{1}{2}$ N-soln. of sodium metaborate, 0.8122; and 0.025N- and a sat soln. of borax dissolved respectively 0.2205 and 1.8285 grms. of gas.

R. Bunsen² measured the solubility of carbon dioxide in ethyl alcohol, and found the solubility to be about twice as great as it is in water; F. Henrich represented these results by the expression $S = 4.3294 - 0.094261\theta + 0.0012354\theta^2$, where S denotes the vols. of carbon dioxide dissolved by one vol. of alcohol. C. Bohr found with 99 per cent. ethyl alcohol

θ	-27°	-20°	-10°	0°	10°	20°	30°	40°	45°
S	38.41	7.51	5.75	4.44	3.57	2.98	2.57	2.20	2.01

where S denotes the number of c.c. of gas at 0° and 760 mm. which 1 c.c. of the liquid dissolves at 760 mm. and θ° . O. Müller found that if water is mixed with alcohol, the absorption coeff. decreases until the mixture contains about 28 per cent. of alcohol; the solubility then increases, attaining the same value with 45 per cent. alcohol as it has for water; the solubility thereafter increases rapidly until it attains the same value as it has for water. Thus, at 20°, the data are:

Alcohol, per cent.	1.07	22.76	28.46	31.17	42.15	71.1	99.7
Absorption coeff.	0.861	0.841	0.792	0.801	0.877	1.283	2.719

O. Lubarsch obtained similar results. W. Kunerth also measured the solubility in ethyl alcohol. B. Schwalbe said that liquid carbon dioxide dissolves in alcohol, and L. P. Cailletet and E. Golardeau noted that the temp. then falls to -72° under atm. press., and to -100° in vacuo. According to W. Hempel and J. Seidel, when aq. alcohol is sat. with solid carbon dioxide a complex $\text{7CO}_2 \cdot 3\text{C}_2\text{H}_5\text{OH} \cdot \text{H}_2\text{O}$ is formed, and when liquid carbon dioxide is distilled into methyl, ethyl, tertiary butyl, or amyl alcohol, and the excess of carbon dioxide is allowed to evaporate, the corresponding alkyl carbonates are formed; with propyl alcohol, the mixture separates into two liquid layers. E. H. Büchner also studied the action of liquid carbon dioxide on *n*-propyl alcohol. J. Zeleny and R. H. Smith found that the addition of alcohol made very little difference to the vap. press. of solid carbon dioxide. A. Findlay and B. Shen, O. Stern, and W. Sander measured the effect of temp. and press. on a number of organic liquids. The first-named found for the solubility, S.c.c. of carbon dioxide per c.c. of liquid at 25° , at *p* mm. press., with aq. alcohol sp. gr. 0.9931 (2.99 grms. per 100 c.c.), and sp. gr. 0.9834 (8.83 grms. per 100 c.c.):

	Sp. gr. 0.9931					Sp. gr. 0.9834				
<i>p</i>	737	836	1073	1338		747	942	1090	1360	
<i>S</i>	0.812	0.813	0.811	0.811		0.786	0.784	0.785	0.788	

A. Findlay and B. Shen found the solubility of carbon dioxide in wort containing 13 grms. of solids per 100 c.c. to be less than in water; and in beer to be less than in a mixture of alcohol and water containing the same proportion of alcohol as that of the beer. The solubility of carbon dioxide in beer has been investigated by T. Langer, and O. Mohr. G. Just found the solubilities of carbon dioxide in methyl alcohol to be 4.606 (15°), 4.205 (20°), and 3.837 (25°) c.c. of gas per c.c. of liquid; in 97 per cent. ethyl alcohol, 3.130 (15°), 2.923 (20°), and 2.706 (25°); in propyl alcohol, 2.498 (25°). F. L. Usher gave 0.868 c.c. for the solubility of carbon dioxide in a 1*N*-soln. of *n*-propyl alcohol. W. Kunerth measured the solubilities in methyl, and amyl alcohols. G. Just found for isobutyl alcohol, 2.088 (15°), 1.964 (20°), and 1.849 (25°); in amyl alcohol, 2.058 (15°), 1.941 (20°), and 1.831 (25°); methyl acetate, 6.494 (25°); isobutyl acetate, 4.968 (20°), and 4.691 (25°); amyl acetate, 4.850 (15°), 4.411 (20°), and 4.119 (25°); and for amyl formate, 4.646 (15°), 4.329 (20°), and 4.026 (25°). O. Stern represented his results with methyl alcohol, ethyl alcohol, acetone, methyl acetate, and ethyl acetate at -59° and -78° in terms of *K* c.c. of carbon dioxide reduced to 0° absorbed by a gram of liquid at the given press., *p*, hence the absorption coeff. is K/D , where *D* is the sp. gr. of the liquid at the given temp. The following values of *K* were obtained at -59° :

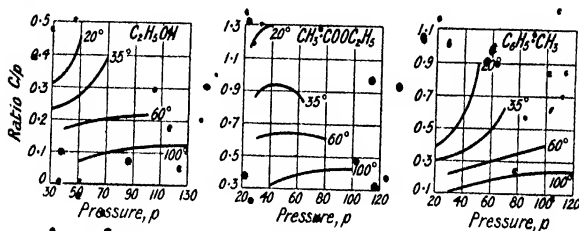

Sp. gr., <i>D</i>	Methyl alcohol.	Ethyl alcohol.	Acetone.	Methyl acetate.	Ethyl acetate.
100 mm.	0.866	0.856	0.879	1.032	0.994
200 mm.	63.0	40.85	97.8	94.30	85.3
400 mm.	64.2	41.00	101.2	98.45	86.3
700 mm.	66.3	42.35	106.6	103.60	91.6
	69.0	44.15	118.8	112.90	101.5

W. Kunerth measured the solubility in amyl acetate. W. Sander expressed his results for ethyl alcohol, propyl alcohol, ethyl ether, ethyl acetate, benzene, chlorobenzene, nitrobenzene, and toluene at 20°, 35°, 60°, and 100° in terms of the number of c.c. of carbon dioxide (reduced to one kgm. per sq. cm.) dissolved by one c.c. of sat. soln. at the given temp. and press.

Temperature, 20°.							
<i>p</i>	Ethyl alcohol.	Propyl alcohol.	Ethyl ether.	Ethyl acetate.	Benzene.	Chlorobenzene.	Bromo-benzene.
20	—	56.16	—	—	71.16	62.61	50.83

Henry's law is not generally applicable at low temp., but in most cases at 100°, the solubility is proportional to the press. for solvents related chemically, e.g. benzene, chlorobenzene, and bromobenzene, and the solubility decreases with increasing mol. wt. B. S. Neuhäuser found the constants of W. A. Patrick's formula—*vide supra*—for methyl and ethyl alcohols respectively $K=0.0126$ and 0.0103 ; and $\gamma^{-1}=0.07$ and 0.055 . The values for the const. C , and press., p , of ethyl alcohol, ethyl acetate, and benzene are plotted in Figs. 52 to 54. A. Christoff found the solubility of carbon dioxide in one p.c. of ethyl-

Figs. 52 to 54.—Solubility of Carbon Dioxide in Ethyl Alcohol, Ethyl Acetate, Toluene.

ether to be 7.330 c.c. at 0°; 6.044 c.c. at 10°; and 5.465 c.c. at 15°; he also measured the solubility of carbon dioxide in mixtures of acetic acid and carbon tetrachloride, and of ethylene chloride and carbon disulphide. K. Ångström gave for the dilation coeff. of soln. of carbon dioxide in methyl alcohol, 0.00184; in ethyl alcohol, 0.00185; and in ether, 0.00200. L. P. Cailletet, B. Schwalbe, and E. H. Büchner said that liquid carbon dioxide dissolves in ether in all proportions. M. Faraday noted that with solid carbon dioxide and ether, the temp. falls to -77° under atm. press.; L. P. Cailletet and E. Colardeau, -77° ; P. Villard and R. Jarry, -79° ; H. V. Regnault, -78.26° ; A. Loir and C. Drion, -81° ; and B. Schwalbe, -77° to -97° ; and in vacuo, M. Faraday obtained -103° ; L. P. Cailletet and E. Colardeau, -103° ; and B. Schwalbe, -110° . L. Bleekrode made some observations on this subject. G. Baumé and F. L. Perrot measured the f.p. of mixtures of methyl ether or methyl alcohol and carbon dioxide. According to W. Hempel and J. Seidel, a solid is formed when aq. ether is sat. with solid carbon dioxide; the composition of the solid varies with the temp. of formation; at a low temp. little else than carbon dioxide is present; the amount of ether, and still more that of water, increases with the temp. of formation; at -50° , the composition is $CO_2.(C_2H_5)_2O.4H_2O$. W. Sander determined the isotherms for sat. soln. of carbon dioxide in ether, and of ether vapour in carbon dioxide at 35°, 60°, and 100°. In the neighbourhood of the critical point, Henry's law is not even approximately valid. G. Just found the solubility in c.c. of gas per c.c. of liquid, of carbon dioxide in acetone to be 0.921 (20°) and 0.295 (25°); ethylene chloride, 4.061 (15°), 3.795 (20°), and 3.525 (25°); ethylene bromide, 2.424 (15°), 2.294 (20°), and 2.167 (25°); chloroform, 3.956 (15°), 3.681 (20°), and 3.430 (25°). W. Kumerth measured the solubility in chloroform, in ethylene bromide, and in acetone. M. Woukoloff found the solubility, S , of carbon dioxide in chloroform at 13° for different press., p mm.:

p	36.57	109.62	255.48	367.64	479.29	589.2	694.98	762.0
S	0.20376	0.92016	1.4875	2.1156	2.7850	3.39003	4.01633	4.43757

F. Dolezalek detected signs of a chemical action. K. Ångström found the dilation coeff. to be 0.00188. G. Just found the solubility of carbon dioxide in carbon tetrachloride, 2.603 (15°), 2.602 (20°), and 2.294 (25°); propylene bromide, 2.586 (15°), 2.426 (20°), and 2.301 (25°); isobutyl chloride, 3.659 (15°), 3.388 (20°), and 3.105 (25°); amyl chloride, 3.363 (15°), 3.127 (20°), and 2.910 (25°); amyl bromide, 2.803 (15°), 2.638 (20°), and 2.455 (25°); dichlorohydrine, 2.034 (15°), 1.917 (20°), and 1.810 (25°); carbon disulphide, 0.9446 (15°), 0.8888 (20°), and 0.8699 (25°). M. Woukoloff found that the solubility of carbon dioxide in carbon disulphide increases approximately proportional with the press., but at low temp. is smaller than is required by Henry's law. G. Just gave for the solubility of carbon dioxide in benzene, 2.710 (15°), 2.540 (20°), and 2.425 (25°); nitrobenzene, 2.845 (15°), 2.655 (20°), and 2.456 (25°); K. Ångström found the dilation coeff. of soln. of carbon dioxide in benzene to be 0.00200, and in nitrobenzene, 0.00168. G. Just gave for the solubility of carbon dioxide in chlorobenzene, 2.581 (15°), 2.420 (20°), and 2.265 (25°); bromobenzene, 2.092 (15°), 1.964 (20°), and 1.842 (25°); iodobenzene, 1.440 (15°), 1.371 (20°), and 1.301 (25°); benzene trichloride, 1.643 (25°); benzyl chloride, 2.180 (15°), 2.072 (20°), and 1.938 (25°); toluene, 2.557 (15°), 2.426 (20°), and 2.305 (25°); benzaldehyde, 3.304 (25°), 3.057 (20°), and 2.841 (25°); aniline, 1.531 (15°), 1.434 (20°), 1.324 (25°). M. Loeb also measured the solubility in aniline; E. H. Büchner, in diphenylamine; and W. Kumerth, in aniline, and benzaldehyde. G. Just gave for the solubility of carbon dioxide in o-

toluidine, 1.539 (15°), 1.473 (20°), and 1.381 (25°); *m-toluidine*, 1.730 (15°), 1.581 (20°), and 1.436 (25°); *pyridine*, 4.291 (15°), 3.862 (20°), and 3.656 (25°); *carvol*, 2.914 (15°), 2.690 (20°), and 2.498 (25°); *cumol*, 1.978 (15°), 1.879 (20°), 1.782 (25°); *eugenol*, 1.762 (15°), 1.653 (20°), and 1.539 (25°); *carvene*, 2.030 (15°), 1.921 (20°), 1.802 (25°); *metazylol*, 2.846 (15°), 2.216 (20°), and 2.090 (25°); and *glycerol*, 0.0302 (25°). W. Kunerth measured the solubility in pyridine. A. von Hammel gave for the absorption coeff. of carbon dioxide in mixtures containing *w* grms. of glycerol per 100 grms. of soln. at 15°:

<i>w</i>	0	26.11	43.72	62.44	77.75	90.74	99.26
Absorption coeff.	1.008	0.785	0.639	0.511	0.430	0.404	0.410

Similarly for *chloral hydrate* at 15°:

<i>w</i>	17.7	31.6	38.3	49.8	57.1	68.8	79.4
Absorption coeff.	0.885	0.803	0.781	0.760	0.765	0.797	0.903

I. F. Hornfray found solid *p-azoxyphenetole* does not absorb carbon dioxide; absorption occurs when the solid is first melted, and an isotropic liquid is formed; then a second increase in absorption occurs; and thereafter the solubility decreases regularly with rise of temp. A. Findlay and B. Shen also obtained values for *chloral hydrate* and *sugar* soln. at 25°. F. L. Usher gave for soln. with 0.125, 0.25, 0.50, and 1.00 mol of *sucrose* per litre, the respective absorption coeff. at 20°, 0.846, 0.815, 0.750, and 0.649; for soln. with 0.5 mol of *dextrose*, 0.792; *mannitol*, 0.782; *glycine*, 0.843; *pyrogallol*, 0.853; *quinol*, 0.887; *resorcinol*, 0.901; *catechol*, 0.868; *urethane*, 0.869; *carbamide*, 0.864; *thiocarbamide*, 0.859; *antipyrine*, 0.859; and *acetamide*, 0.879. S. Gnievysz and A. Walfisz found the absorption coeff. of *petroleum* to be 1.31 at 10° and 1.17 at 20°.

The action of carbon dioxide on *blood* has been studied by S. Jolin,⁶ L. Meyer, J. Setschenoff, etc. G. Geffcken⁷ measured the solubility of carbon dioxide in *colloidal solutions* of arsenic sulphide, and of ferric hydroxide. A. Findlay and co-workers have also measured the effect of colloids and fine suspensions on the solubility of carbon dioxide in water at 25° and various pressures. The solubility increased slightly with increasing conc. of ferric hydroxide, gelatin, silicic acid, aniline, methyl orange, blood serum, peptone, protopeptone, and haemoglobin; while the solubility diminishes slightly with increasing conc. of arsenious sulphide, dextrine, soluble starch, glycogen, egg-albumen, and serum-albumen. No perceptible effect was observed with silica or charcoal suspensions. When the solubility is increased by a given substance, the solubility curve is depressed with an increase of pressure, and conversely. In the case of starch, and other neutral colloids, the solubility passes through a minimum with an increase of pressure. A. Findlay and G. King made observations on the influence of suspensions and colloids on the evolution of carbon dioxide from supersaturated soln.

Special observations on the adsorption of carbon dioxide by *charcoal* were made by P. A. Favre and J. T. Silbermann,⁸ J. Hunter, L. Joulin, H. Kayser, L. B. Richardson and J. C. Woodhouse, P. Chappius, A. Reychler, R. A. Smith, M. W. Travers, J. Dewar, J. L. Bärrwald, E. W. R. Pfeiffer, etc. They showed the effect of pressure and temperature on the adsorption by different kinds of charcoal. These results have been previously discussed in connection with carbon. Similarly also with the thermal effect studied by P. A. Favre and J. T. Silbermann, P. Chappius, J. Dewar, etc. With a mixture of 95 per cent. hydrogen and 5 per cent. carbon dioxide, R. Lorenz and E. Wiedbrauck found that there is a high proportion of hydrogen adsorbed at first, the amount then falls rapidly; while with carbon dioxide, the proportion adsorbed at first is small, but rises rapidly. J. Böhm discussed the adsorption of carbon dioxide by *coal*. C. Matignon and G. Marchal examined the corrosive action of carbon dioxide under 10 atm. pressure during three years on *quartz*, *mica*, *diopase*, *wollastonite*, *talc*, *asbestos*, and *glass*. J. B. Hannay found that glassy *silicates*, *borates*, and *phosphates* adsorb carbon dioxide under pressure. He also found that glass at about 200° and 200 atm. pressure readily adsorbs carbon dioxide, and retains much gas when cooled under pressure; if the glass be then rapidly heated to fusion, the sudden evolution of the gas makes the glass froth; whereas if slowly heated to 300°, the gas is given off without any appreciable effect. H. Kayser, J. T. Bottomley, L. Pfandler, O. Schumann, H. Krause, also studied the adsorption of carbon dioxide by the walls of glass vessels, and by glass powder. R. Bunsen made observations extending over three years, and concluded: (1) The gas condensation does not reach a fixed point, even after several years; (2) during the continuation

of the experiment, notwithstanding instantaneous or continual changes of temp. and press., no giving up of the carbon dioxide was observable; (3) within temp. of $+23^{\circ}$ to -8° a rise of temp. produces an acceleration, a fall a corresponding retardation of the adsorption. In three years 5.135 c.c. of carbon dioxide under standard conditions were adsorbed by one metre of the glass wool. As the chemical affinity of the silica for the basic substances in the glass is greater than that of the carbon dioxide, the supposition of a combination of the latter with the glass is precluded; thus it appears that the carbon dioxide is condensed as such. The long continuation of this phenomenon can be explained by an imperfect interpenetration of the glass by the molecules of the liquid carbon dioxide. It was not proved whether after a sufficiently long interval of time this interpenetration becomes negligibly small so that the conditions remaining the same, neither condensation nor evaporation of the liquid carbon dioxide takes place, although either one or the other might be caused by a change of the conditions. For every series of temp. there may be a corresponding series of levels of the layer of the carbon dioxide. Atm. air behaves like carbon dioxide. F. Scheermesser found that sand, washed with hydrochloric acid and then calcined, slowly adsorbs traces of carbon dioxide, and mixtures of sand and clay adsorb more gas when moist than when dry; the gas is given off in sunlight and re-adsorbed in the shade. J. H. van den Broek, and J. Nicklès studied the adsorption of carbon dioxide by soils; G. Hüfner, the adsorption of carbon dioxide by hydrophane (opal); and L. A. Munro and F. M. G. Johnson, the adsorption of the gas by alumina.

S. von Wroblewsky, A. Reythler, and W. Hempel found that caoutchouc or rubber adsorbs carbon dioxide, and the first-named added that the phenomenon is purely physical, not chemical. J. D. Edwards and S. F. Pickering found the relative permeability of rubber to hydrogen and carbon dioxide is as 1 : 2.9; the rate of diffusion at 100° is about 17 times that at 0° . The permeability varies somewhat with the composition and age. According to G. Hüfner, grey caoutchouc absorbs nearly its own vol. of carbon dioxide at -2° , and the sp. absorption coeff. increases with a rise of temp. T. Graham found that silver adsorbs 0.486 to 0.545 vol. of carbon dioxide, and gold, 0.16 vol., and G. Neumann added that he found that 29 grms. of copper occluded 0.0055 to 0.0196 grm. of the gas. A. Sieverts and W. Krumhaar found that carbon dioxide dissolves neither in molten nor in solid copper. H. S. Taylor and R. M. Burns studied the adsorption of carbon dioxide by nickel, cobalt, iron, copper, palladium, and platinum—vide the respective metals—and by copper, manganese, cobalt, and silicon oxides.

Liquid carbon dioxide is a poor solvent. G. Gore⁹ found that it dissolves camphor and iodine sparingly, it dissolves fats less rapidly than carbon disulphide. It changes gutta-percha into a brown coloured substance; and it makes rubber swell. L. P. Cailletet said that it does not dissolve sodium or calcium chloride, sodium sulphate, calcspar or chalk, stearin, paraffin, sulphur, or phosphorus. It changes potassium carbonate into the hydrocarbonate; it dissolves iodine, and fatty oils sparingly. P. Villard also made some observations on this subject. C. Doelter studied the action of liquid carbon dioxide and water on silicates. E. H. Büchner found that it does not dissolve sodium, calcium, and mercuric chlorides, potassium bromide, or potassium and mercuric iodides; cupric or ferrous sulphate; silver nitrate; sodium or calcium carbonate; mercuric cyanide, silica, arsenic trioxide, metaphosphoric acid, sodium or calcium phosphide, phosphorus sulphide; potassium fluosilicate; quaternary ammonium salts; carbon; silicon; aluminium; sulphur; potassium; or sodium. The following are sparingly soluble in this menstruum: phosphorus, iodine, bromine, boric acid, phosphorus pentachloride, and antimony and arsenic tribromides. The following are completely miscible with the liquid: acetylene, pentane, amylene, benzene, *p*-xylene, *p*-dichlorobenzene, acetic acid, camphor, and carbon disulphide; the following are partially miscible: anthracene, phenanthrene, tri-iodomethane, *p*-dibromobenzene, *p*-chloro- or bromo-nitrobenzene, 1,2,3- and 1,3,2-dichloronitrobenzene, borneol, phthalic anhydride, succinic anhydride, urea, and benzamide. The following have a limited solubility: tribromomethane, *o*-bromo-nitrobenzene, mono- and di-chloronitrobenzene, nitrobenzene, thymol, and urethane.

• § 36. The Chemical Properties of Carbon Dioxide

The dissociation of carbon dioxide by heat has been described in connection with the action of oxygen on carbon. F. Haber and H. le Rossignol investigated the dissociation of carbon dioxide in the flame of burning carbon monoxide mixed with oxygen. According to S. Chadwick, J. E. Ramsbottom, and L. L. Chapman,¹ dry carbon dioxide gas exposed to ultra-violet light is partially resolved into carbon monoxide and oxygen. There is a 3 per cent. decomposition under atm. press., and a 46 per cent. decomposition under 36 mm. press. The moist gas was not decomposed under these conditions. Probably some ozone is also formed. H. Herchfinkel obtained similar results, and observed that the surface of the mercury confining the gas acquired a yellow film of mercuric oxide. According to A. Coehn and G. Sieper, with dry carbon dioxide there was an 18 per cent. decomposition, and when the merest trace of moisture was present, a 0.10 per cent. decomposition. Neither formic acid nor formaldehyde was formed. The water was not changed. The decomposition was inversely proportional to the press. and more than corresponded with the law of mass action. H. Tramm showed that the speed of combination of carbon monoxide and oxygen in ultra-violet light is the same for the moist or dry gas; the retarding effect of moisture on the photo-decomposition of carbon dioxide is not due to an acceleration in the formation of carbon dioxide but to a retardation in its decomposition. Sulphur dioxide acts like water as a retarder—vide the oxidation of carbon monoxide; and J. Pello found that potassium cyanide inhibits the reaction.

The readiness with which carbon dioxide can be reduced to formaldehyde is considered to be most suggestive in revealing the mechanism of photosynthesis. This led R. Willstätter and A. Stoll to conclude that carbonic acid is rearranged by the absorption of light energy into a formaldehyde peroxide complex from which, by means of an enzyme-catalase-action, formaldehyde is liberated, oxygen evolved, and chlorophyll regenerated. E. Bauer and P. Büchi found no evidence of the formation of formaldehyde, oxalic acid, or formic acid in the photolysis of carbonic acid; the production of formaldehyde—reported by E. C. C. Baly and co-workers—when carbonic acid, in the presence of a sensitive dye, is exposed to light was said to be due to the decomposition of the dye itself. O. Loew found that carbon dioxide in the presence of water is not reduced by exposure to sunlight. A. Lieben found no formic acid was produced after 50 hrs. exposure to sunlight. According to A. Bach, a stream of purified carbon dioxide was passed through two flasks, each containing a 1.5 per cent. soln. of uranium acetate. One flask was exposed to direct sunlight; the other was covered with black paper to exclude light. The contents of the flask containing the soln. treated with carbon dioxide and exposed to sunlight alone became turbid and of a more or less greenish colour in about 20 mins.; after some time, there was a considerable deposit, which, when filtered and washed, had a violet colour. This precipitate, when exposed to air, became yellow, and was transformed into a mixture of uranous and uranic hydroxides, with a trace of a brownish-yellow substance, probably uranium peroxide. When the uranium peroxide was exposed to the action of hydrogen peroxide and formaldehyde, the yellowish

precipitate acquired a greenish colour, and was finally transformed into the violet-brown substance soluble in acetic acid. A. Bach explained the results by assuming that a soln. of carbonic acid in sunlight slowly forms percarbonic acid and formaldehyde, $3\text{H}_2\text{CO}_3 = 2\text{H}_2\text{CO}_4 + \text{H.CO.H}$; and the percarbonic acid then decomposes into hydrogen peroxide, etc., $\text{H}_2\text{CO}_4 = \text{CO}_2 + \text{H}_2\text{O}_2$. R. Wolfenstein and E. Peltner¹ could not prove the formation of the percarbonic acid. A. Bach showed that carbon dioxide and water in the presence of a dil. sulphuric acid soln. of dimethyl aniline (A. Trillat's test), give the intense blue reaction characteristic of formaldehyde, after exposure to light—diffused daylight or even the light from a gas-flame is sufficient. H. Euler said that the reaction does not occur with freshly purified dimethylaniline; and he found that when a soln. of uranium acetate is exposed to sunlight, it gave in one hour the same precipitate of uranous and uranic hydroxides as was obtained in half an hour from the soln. exposed to the action of sunlight and carbon dioxide. The function of the carbon dioxide is to remove oxygen from the soln., and it may be replaced by another indifferent gas, such as hydrogen or nitrogen. H. A. Spöhr repeated the experiments of F. L. Usher and J. H. Paestley, D. Berthelot and H. Gauduchon, J. Stoklasa and W. Zdobnický, and E. G. C. Baly and co-workers, and has failed to obtain evidence of the reduction of carbon dioxide to formaldehyde; but A. K. Sanyal and N. R. Dhar found that the exposure of moist carbon dioxide for 72 hrs. to tropical sunlight produced appreciable quantities of formaldehyde. Carbon dioxide is reduced by hydrogen to formic acid in the presence of palladium black; the reaction is reversible, and there is no sign of the intermediate product, formaldehyde. E. Baur and co-workers could not confirm the photocatalysis of carbon dioxide by colloidal iron or uranium oxides, ferric chloride, or sodium uranate, as reported by B. Moore and T. A. Webster. The reaction was investigated by T. Thunberg, F. Weigert, H. H. Dixon and N. G. Ball. O. Warburg and E. Negelein investigated the effect of the wave-length of light on the assimilation of carbon dioxide. The yield is greatest in the red and least in the blue region. R. Wurmser also compared the effects of red, green, and blue light.

Carbon dioxide was found by W. Ramsay² and co-workers to be decomposed into carbon, carbon monoxide, and oxygen when exposed to radium radiations. E. Wourtsel found that the action is very slow. H. Herchfinkel said the reaction resembles that which occurs on exposing the gas to ultra-violet light, and that about one-hundredth of the carbon dioxide is reduced to monoxide. B. Walter also found that the radiations from radio-tellurium acted like ultra-violet light on carbon dioxide. According to U. Bergell, solid carbon dioxide absorbs radium emanation, and, on sublimation, the last fraction of the gas is radioactive.

In 1788, M. Laviatriani,³ and, in 1785, M. van Marum observed that carbon dioxide is decomposed by frictional electricity, for the vol. of the gas is permanently increased, and it is no longer so readily absorbed by water. J. Dalton, W. Henry, and J. Plücker noticed that the passage of electric sparks through carbon dioxide decomposed the gas into carbon monoxide and oxygen. W. Henry said:

When the electric shock has been repeatedly passed through a portion of this acid gas, its bulk is enlarged, and a permanent gas is produced which is evidently a mixture of oxygenous and hydrogenous gases; for, when an electric spark is passed through the gas that remains after the absorption of the carbonic acid by caustic alkali, it immediately explodes.

The decomposition, said H. St. C. Deville, is but slight because the spark also causes the products of the reactions to re-form carbon dioxide: $2\text{CO} = 2\text{CO} + \text{O}_2$. Observations were also made by A. W. Hofmann, B. Lepsius, M. Berthelot, T. Andrews and P. G. Tait, H. B. Dixon and H. F. Lowe, etc. H. Buff and A. W. Hofmann showed that when the decomposition of the carbon dioxide has progressed for some time, the resulting carbon monoxide and oxygen recombine with explosive violence. A. W. Hofmann showed that the explosion occurs only

under special conditions, the spark should be 2.5 to 3.0 mm. long when the current is derived from two Bunsen's cells, connected with a Ruhmkoff's coil and a small Leyden jar. A. Smithells suggested carbon dioxide at low press. in a vacuum tube may be fairly stable in the electric discharge, but J. N. Collie found that under these conditions decomposition to the extent of 65 per cent. may occur in 10 secs. There is evidence of recombination because, during the passage of the discharge, flickerings occurred in the tube when the negative electrode became hot, and the glow on the hot negative electrode changed from the livid blue exhibited by the mixture of decomposed gases to the purple colour, which was characteristic when the gas was first subjected to the electric discharge. The results are independent of the electrode, and from 50 to 62 per cent. is found to have decomposed when the gas at 5-6 mm. press. is confined in an electrodeless tube. No difference was observed whether the undried or specially dried gas was employed. A. W. Hofmann found that in the electric arc with iron electrodes the gas decomposed yielding its own vol. of carbon monoxide, while if the iron contained carbon, more carbon monoxide was formed. B. Lepsius found that with carbon electrodes one vol. of carbon dioxide yields two vols. of carbon monoxide. C. Montmartin found that the corona effect in circuits traversed by a continuous current decomposes carbon dioxide into oxygen and carbon monoxide.

T. Andrews and P. G. Tait found that carbon dioxide is slowly decomposed by the silent discharge—in, say, an ozone tube—and a bronze-green deposit appears on the anode. A. Thénard observed that carbon monoxide and oxygen are formed, and that the latter is partly converted into ozone. W. Lob said that the ozone which is formed re-oxidizes the carbon monoxide. Observations were made by B. C. Brodie, P. Hautefeuille and J. Chappius, E. Reitlinger and A. von Urbanitzky, A. W. Hofmann, etc. M. Berthelot noted the formation of solid carbon oxide—vide carbon suboxides. A. Holt found that the amount of decomposition is less the weaker the discharge, or the wider the annular space in the ozonizer; and with a discharge of constant intensity and at varying press., the amount of dried gas decomposed varies inversely as the press., while with moist gas, the amount decomposed varies directly as the press.:

Pressure	30	165	300	652	50	220	448	628
Decomposition	48.4	31.0	19.9	2.6	3.8	5.5	10.3	14.0 per cent.
	Dried gas				Moist gas			

It is assumed that in the moist gas at low press. the discharge is almost entirely due to ultra-violet light, but, as the press. increases more and more, sparks are formed which decompose the gas. T. Noda and E. Warburg found that with a point discharge, the carbon dioxide is decomposed to the extent of 3 per cent., and that about 19 per cent. of the oxygen produced is ozonized. The number of coulombs required to decompose a gram-eq. of carbon dioxide is only 2610, which shows that the decomposition of this gas by the silent discharge is not an electrolytic process. It is shown also that of the electrical energy supplied only 1.1 per cent. is converted into chemical energy. For a negative point discharge, it appears that the amount of decomposition depends only on the total electricity, not on the current strength. Further, the number of coulombs per mol. of carbon dioxide decomposed increases as the density of the gas is diminished. It is also found that the number of coulombs falls off as the temp. rises.

In 1802, N. T. de Saussure observed that when electric sparks are passed through a mixture of hydrogen and carbon dioxide, the vol. decreases. A similar observation was made by M. Traube, A. Naumann and C. Pistor, etc. J. N. Collie found that with the electric discharge at low press. the carbon monoxide formed *in statu nascendi* did not produce any detectable amount of formaldehyde, but the decomposition of the carbon dioxide appeared to be retarded by the hydrogen. C. Zenghelis said that the gases in a nascent state owe their activity to their being in an extremely finely-divided condition because carbon dioxide in a sat. aq. soln. is

reduced by hydrogen passed into the soln. through filter-paper, or parchment. The action is accelerated by sunlight or ultra-violet light. Formaldehyde is the first product of the action. Carbon dioxide is slowly reduced by hydrogen when both gases are present in the same aq. soln.

S. M. Losanitsch and M. Z. Jovitschitsch found on exposing a mixture of carbon dioxide and hydrogen to the silent discharge, some formic acid is produced. M. Berthelot said that some carbohydrates are formed when the hydrogen is in excess: $n\text{CO}_2 + 2n\text{H}_2 = \text{C}_n\text{H}_{2n}\text{O}_n + n\text{H}_2\text{O}$; if less hydrogen is present, the product is richer in oxygen; and if nitrogen be present a nitrogenous product, $(\text{COH}_3\text{N})_n$, or $(\text{COH}_3\text{N})_n + n\text{H}_2\text{O}$, is formed, while in the presence of water, ammonium nitrate appears. W. Löb also noted that some formic acid is produced by the action of the silent discharge on a moist mixture of carbon dioxide and hydrogen, and hydrogen peroxide was detected, but some ozone was formed, and this appears to hinder or prevent the formation of hydrogen peroxide. He represents the reactions: $2\text{CO}_2 = \text{C}_2\text{O}_2 + \text{O}_2$; $2\text{H}_2 + \text{O}_2 = 2\text{H}_2\text{O}$; $\text{H}_2 + \text{CO} = \text{HCOH}$; $\text{CO} + \text{H}_2\text{O} = \text{HCO.OH}$; and possibly also $\text{CO}_2 + \text{H}_2 = \text{HCO.OH}$. No glycolaldehyde was detected. E. Royer found formic acid is produced when carbon dioxide is passed into water contained in the porous pot of Bunsen's or Grove's cell; and that more is formed with un-amalgamated than with amalgamated zinc. H. Thiele observed no result when a mixture of hydrogen and carbon dioxide in a quartz bulb is exposed to ultra-violet light; but A. Coehn and G. Sieper observed that formaldehyde is produced with a mixture of equal vols. of carbon dioxide and hydrogen.

A. Schrötter found that at a dull red heat carbon dioxide is reduced by hydrogen to carbon monoxide; G. Gore added that the reduction does not proceed so far as to give carbon. A. Naumann and C. Pistor observed no reduction at 900° , and C. Hoitsenia said that the mixture: $\text{CO}_2 + \text{H}_2 = \text{CO} + \text{H}_2\text{O}$ can be kept a long time at 600° without attaining a state of equilibrium. According to M. Berthelot, when a mixture consisting of carbon dioxide and hydrogen is raised to a high temp., the state of equilibrium is established, not between the binary systems $(\text{CO}_2 + \text{H}_2)$ and $(\text{CO} + \text{H}_2\text{O})$, but between the more complicated system $\{(n-a)\text{CO}_2 + a(\text{CO} + \text{O})\}$, resulting from the partial dissociation of carbon dioxide and the partial dissociation of steam, $\{(m-\beta)\text{H}_2\text{O} + \beta(\text{H}_2 + \text{O})\}$, while a further complication results from the dissociation of carbon monoxide which reacts in the following sense, $\{p(\text{O}) = (p-2)(\text{O}) + (\text{O}_2 + \text{C})\}$. O. Boudouard found that different mixtures of hydrogen and carbon dioxide at 850° and at 1100° attained a state of equilibrium in a few hours, and the distribution of the products $\text{CO}_2 + \text{H}_2 = \text{CO} + \text{H}_2\text{O}$ were in accord with H. Le Chatelier's theorem. Press. had no influence on the equilibrium conditions since the number of reacting mols. is the same as the number produced by the reaction. The conditions of equilibrium have been discussed in connection with the reverse reaction between carbon monoxide and steam.

Reduced iron was found, by P. Sabatier and J. B. Senderens, and A. Gautier and P. Clausmann, to act catalytically on the reduction of carbon dioxide by hydrogen at 420° , forming methane. P. Sabatier and J. B. Senderens found that reduced cobalt at 300° begins to form methane, and at 360° - 400° , the reaction is rapid; reduced nickel begins to act at 230° , and at 300° the reaction $\text{CO}_2 + 4\text{H}_2 = \text{CH}_4 + 2\text{H}_2\text{O} + 41.2 \text{ Cals.}$ occurs. S. Medsforth studied the action of nickel, and the effect of the oxides of Ce, Th, Be, Cr, Al, Si, Zr, Mo, V, Sn, Mg, Cu, and Ag on the nickel catalyst. H. S. Elworthy and E. H. Williamson patented the application for manufacturing methane. M. Mayer and co-workers also studied the reaction. P. Sabatier and J. B. Senderens found reduced copper acts catalytically, $\text{CO}_2 + \text{H}_2 = \text{CO} + \text{H}_2\text{O}$; and that there is no appreciable formation of methane with finely divided platinum or palladium at 420° . E. Orloff found that carbon dioxide is not reduced to formaldehyde by nickel or palladium at 95° - 100° , but at higher temp. methane and ethane are formed. According to A. Bach, when carbon dioxide is reduced by hydrogenized palladium, formaldehyde is produced. H. B. Dixon observed the reduction of carbon monoxide by hydrogen when a

platinum spiral is electrically heated to redness in the mixed gases. E. Müller and H. Barck found that the reduction of carbon dioxide by hydrogen is greatly accelerated in the presence of chromium and iron; with manganese, some carbide is formed. A. P. Dubrunfaut found that when hydrogen is passed over calcium carbonate at a red heat, carbon and water are formed; similarly also when a mixture of carbon dioxide and hydrogen is passed over red-hot pumice, he said that the reduction occurs in two stages: $\text{CO}_2 + \text{H}_2 = \text{H}_2\text{O} + \text{CO}$, and $\text{CO} + \text{H}_2 = \text{C} + \text{H}_2\text{O}$.

According to R. Bunsen, if a mixture of hydrogen, oxygen, and carbon dioxide be inflamed, the ratio of the reduced to the non-reduced carbon dioxide changes *per saltum* when different proportions of the combustible gases are employed. On the contrary, A. Horstmann showed that the results are quite in agreement with the law of mass action, in which the equilibrium concerned is: $\text{CO}_2 + \text{H}_2 = \text{H}_2\text{O} + \text{CO}$. M. Berthelot said that if the mixture burns explosively, the carbon dioxide is not changed, and only when the combustion proceeds slowly is carbon monoxide formed. He also found that when a mixture of equal vols. of carbon dioxide and oxygen in sealed tubes was exposed to the action of a silent discharge, 16 per cent. of the gas was decomposed with the formation of a gas acting as a strong oxidizing agent. If this gas be regarded as ozone then it is produced in the proportion of from 30 to 40 per cent. of the amount of oxygen set free, which is larger than the quantity of ozone formed from pure oxygen. All attempts to isolate the gas have failed, owing to its strong oxidizing properties, and it is suggested that possibly percarbonic acid is formed.

According to A. Lieben,⁵ at ordinary temp. hydrogen *in statu nascendi* does not reduce carbon dioxide dissolved in water, nor did W. Löb detect the formation of perceptible amounts of formaldehyde or formic acid under these conditions. A. Lieben, however, observed that carbonates of the alkalis or alkaline earths (not magnesium hydrocarbonate) are reduced to formates by hydrogen *in statu nascendi* derived from the action of magnesium or platinized magnesium. Light has no effect on the reaction. H. Moissan found that the alkali hydrides—sodium, potassium, rubidium, cesium—do not react with thoroughly dried carbon dioxide at ordinary temp.; but, in the presence of the merest trace of water, between -85° and $+54^\circ$, potassium hydride and carbon dioxide form potassium formate. M. Mayer and V. Altmayer found that calcium hydride reacts with carbon dioxide: $4\text{CaH}_2 + 2\text{CO}_2 = \text{CH}_4 + 4\text{CaO} + \text{C} + 2\text{H}_2$.

S. M. Losanitsch and M. Z. Jovitschitch⁶ found that carbon dioxide and water vapour react under the influence of the silent discharge, producing formic acid, ozone, and hydrogen dioxide. W. Löb made similar observations—*vide supra*. For the action of hydrogen peroxide, *vide* percarbonates. The solubility of carbon dioxide in water has been previously discussed. An aq. soln. of carbon dioxide has the properties of a weak acid—*vide* the conductivity of the aq. soln. At atm. press., the aq. soln. gives a claret-red with blue litmus; and, according to F. J. Malaguti, at a press. of two atm., the red colour is more marked. R. Kersting said that water containing 0.000004 part of carbon dioxide will colour neutral litmus violet. According to J. B. A. Dumas and J. S. Stas, and H. St. C. Deville, a soln. coloured claret-red by litmus has its original colour restored by exposure to air, owing to the escape of carbon dioxide. The colour is quickly discharged by boiling the soln. According to F. A. Flückiger, and H. Rebenstörff, a soln. of phenolphthalein reddened by sodium hydroxide is decolorized by carbon dioxide. The colour with methyl orange is scarcely affected by carbonic acid, but B. von Szyzkowsky found a sat. soln. of sodium chloride coloured with methyl orange is more sensitive to carbonic acid than is an aq. soln. The feeble acidity of carbonic acid explains why only the more electropositive metals are affected by this acid—*vide* the action of the metals on carbonic acid. Carbonic acid is stronger than tartaric acid (D. A. Goldammer), nitrous acid (C. Marie and R. Marquis, J. Meunier, and R. B. Moore), and boric acid (L. Grünhut). R. Höber studied the effect of carbonic acid on the alkalinity of blood.

H. Moissan⁷ found that at ordinary temp. fluorine does not react with carbon dioxide. J. Schiel found that carbonyl chloride is formed when a mixture of carbon dioxide and chlorine is passed over red-hot carbon. According to R. Lucien, dry chlorine at 300° and at a bright red heat is without action on carbon dioxide. With chlorine and moist carbon dioxide, however, hydrogen chloride is formed in the usual way; 55 per cent. of the chlorine disappeared in this way when the carbon dioxide was mixed with 8 per cent. of chlorine; when, however, the chlorine formed only one per cent. of the mixture, then only 11 per cent. of it was converted into hydrogen chloride. With air as diluent, just the reverse took place, and the percentages of chlorine attacked were 14 in the first instance and 80 with the one per cent. mixture. According to J. Dewar, carbon dioxide mixed with many substances and at high press. behaves as if it formed unstable compounds which are decomposed and reproduced according to the conditions of the experiment; with bromine at 40° and 60 atm. press., two distinct layers are formed one of which is liquid carbon dioxide with a little bromine in soln.; at 90 atm. press. the two liquids are miscible; with carbon dioxide and hydrogen chloride liquefaction occurs at

	0°	5 0°	8 0°	10 1°	18 5°	34 0°	35 0°
Pressure . . .	36.0	39.0	43.8	48.2	59.0	83.0	90.0 atm.

H. Müller stated that an aq. soln. of sodium chloride is decomposed by carbon dioxide with the evolution of hydrogen chloride, and H. Schulz said that if a 5 per cent. soln. be tinted with 0.001 per cent. of methyl violet, the colour is destroyed by passing carbon dioxide through the soln. J. Röhmman and E. Malachowsky added that the decoloration is really due to the precipitation of the methyl violet by the salts in soln. N. N. Beketoff observed no change when a dil. soln. of barium chloride or calcium chloride is treated with carbon dioxide under 40-45 atm. press. H. Müller, however, observed that lead chloride gives a precipitate of lead chloro-carbonate. W. Spring found that when carbon dioxide is passed over lead chloride at 400°-500°, chlorine is given off. H. Struve, and G. Pellagri found that potassium iodide, in the presence of water, is decomposed by carbon dioxide, and, added G. Papasogli, if the potassium iodide is quite pure, no decomposition occurs at ordinary temp., but at a higher temp., hydrogen iodide is set free.

A. J. Balard found that hypochlorites are decomposed by carbon dioxide, and chlorine monoxide is set free. J. L. Gay Lussac found that the reaction is incomplete when the hypochlorites are in soln. A. W. Williamson studied the action of carbon dioxide on barium hypochlorite; and J. Kolb, H. G. de Claubry, A. Morin, and C. Göpner the action on calcium hypochlorite (*q.v.*). N. A. E. Millon stated that the chlorites are decomposed by carbon dioxide. According to G. Papasogli, and C. F. Cross, potassium iodate alone is not decomposed by carbon dioxide, but if some potassium iodide is also present, iodine is set free. M. Gröger found that the reaction is incomplete.

G. Chevrier⁸ found that carbonyl sulphide (*q.v.*) is formed when a mixture of sulphur vapour and carbon dioxide is exposed to the silent discharge; and A. Cossa found that the same product is obtained when carbon dioxide acts on boiling sulphur. M. Berthelot, however, said that dry carbon dioxide has no action on boiling sulphur, and that the small quantity of carbonyl sulphide which is formed when a mixture of sulphur vapour and carbon dioxide is passed through a red-hot porcelain tube is derived from the carbon monoxide produced by the dissociation of the carbon dioxide. S. Petuchoff could detect no carbon as a result of this operation. A. Smith and W. B. Holmes showed that when molten sulphur is treated with carbon dioxide it does not give the insoluble form when cold. S. Petuchoff found that at 1200°, sulphur, and carbon dioxide derived from the decomposition of carbonates, produces carbon monoxide, sulphur dioxide, and carbon. H. Köhler passed a mixture of carbon dioxide and hydrogen sulphide through a red-hot tube and found sulphur, carbon monoxide, and water are formed: $\text{CO}_2 + \text{H}_2\text{S} = \text{CO} + \text{H}_2\text{O} + \text{S}$.

The reaction is possibly : $\text{CO}_2 + \text{H}_2\text{S} = \text{COS} + \text{H}_2\text{O}$, but the carbonyl sulphide is decomposed at the temp. of the experiment. A. Gautier represented the reaction : $6\text{CO}_2 + 9\text{H}_2\text{S} = 3\text{COS} + 5\text{CO} + \text{H}_2 + 8\text{H}_2\text{O} + 6\text{S}$; no hydrocarbons were found. M. Berthelot found that when a mixture of carbon dioxide and hydrogen sulphide is exposed to the silent discharge, each gas is decomposed separately and the products react, forming sulphur dioxide, and trioxide. B. Holmberg noted that when carbon dioxide is passed into an alcoholic soln. of potassium hydrosulphide, potassium ethylcarbonate, potassium hydrocarbonate, etc., are formed : $\text{KSH} + \text{CO}_2 + \text{C}_2\text{H}_5\text{OH} = \text{KO} \cdot \text{CO} \cdot \text{OC}_2\text{H}_5 + \text{H}_2\text{S}$; and $\text{KSH} + \text{CO}_2 + \text{H}_2\text{O} = \text{H}_2\text{S} + \text{KHCO}_3$. E. Berl and A. Rittener represent the action of carbon dioxide on sodium sulphide at 14° and 80° by : $\text{Na}_2\text{S} + \text{CO}_2 + \text{H}_2\text{O} = \text{NaSH} + \text{NaHCO}_3$, and $\text{NaSH} + \text{CO}_2 + \text{H}_2\text{O} = \text{NaHCO}_3 + \text{H}_2\text{S}$ respectively. E. Berl and A. Rittener, and L. A. Buchner studied the action of carbon dioxide on calcium hydrosulphide, $\text{Ca}(\text{SH})_2$; and M. Berthelot, the action on potassium polysulphide. The physical properties of mixed carbon dioxide and sulphur dioxide have been previously discussed—*vide supra*, and 1. 4, 8. M. Berthelot found that when potassium sulphite or hydrosulphite is heated to redness in a stream of carbon dioxide, the alkali sulphate, polysulphide, and a little carbonate are formed; while under similar conditions carbon dioxide does not act on potassium sulphate. J. Davy said that water sat. with carbon dioxide under press. has no more action on dihydrated calcium sulphate than has water alone.

N. T. de Saussure⁹ observed that carbon dioxide is reduced to carbon monoxide when heated in the presence of carbon. V. A. Jacquelin studied the slow combustion of carbon in an atm. of carbon dioxide when heated by the oxyhydrogen flame, or by the carbon monoxide-oxygen flame. A. P. Dubrunfaut stated that if hydrogen or moisture be excluded, carbon does not reduce carbon dioxide. J. B. A. Dumas said that at a red heat the reduction of dried carbon dioxide is effected by dried carbon. This subject has been discussed in connection with the action of oxygen on carbon. B. Rathke gave for the heat of reduction $\text{CO}_2 + \text{C} = 2\text{CO} - 36.7$ Cals., and stated that the reaction is incomplete at a red heat. According to B. Unger, the reduction does not occur at 960° ; this statement, however, is not correct. P. Sabatier and J. B. Senderens could detect no action between 230° and 400° ; A. Naumann and C. Pistor said that the reaction sets in about 550° ; O. Boudouard said that no reduction is appreciable below 450° , and at 950° the reaction is complete. The reversibility of the reaction was established by H. St. C. Deville about 1864, and the equilibrium conditions have been discussed in connection with the action of oxygen on carbon. H. von Jüptner studied the equilibria of the gases in gas producers. C. A. Parsons showed that when carbon is electrically heated in an atm. of carbon dioxide under press., carbon monoxide is almost wholly formed. M. Foix found that the diamond has practically no action on carbon dioxide, so that the reaction $\text{CO}_2 + \text{C}_{\text{diamond}} = 2\text{CO}$ is not reversible. G. Gore observed no reduction of carbon dioxide to carbon when it is heated with hydrocarbons. J. Lang found that the reduction of carbon dioxide by methane begins between 700° and 800° ; the reaction is very slow between 703° and 814° ; above this, carbon monoxide is formed in proportions increasing with the rise of temp., and some carbon is formed above 1000° . P. and A. Thénard observed that a mixture of carbon monoxide and methane in the silent electric discharge gives a liquid product; and W. Löb showed that carbon monoxide and hydrogen are formed. A. Frank observed that when a mixture of acetylene and carbon dioxide is heated, or exposed under press. to the silent discharge, amorphous carbon is formed : $2\text{C}_2\text{H}_2 + \text{CO}_2 = 2\text{H}_2\text{O} + 5\text{C}$. J. Dewar found that when equal vols. of acetylene and carbon dioxide are liquefied, the incompletely miscible liquids mix completely at 13° and 25.23 atm., 26.8° and 34.1 atm., 41° and 75.52 atm. Similar phenomena were observed with carbon dioxide and benzene, and S. Miyamoto found that a silent discharge through the vapour of benzene and carbon dioxide forms a phenol, $\text{C}_{30}\text{H}_{30}\text{O}_9$. W. Löb observed that the action of the silent discharge on a mixture of ethyl alcohol, carbon dioxide, and water vapour gave much carbon monoxide, some formal-

dehyde, and formic acid, and traces of acetaldehyde. J. Dewar found that with mixtures of carbon dioxide and ether, at 20° and 20 atm. the gases condense to a liquid in which the two constituents are miscible in all proportions, a separation occurs at 42° and 55 atm., and at 68° and 110 atm. J. Dewar, and J. P. Kuenen studied the condensation phenomena with mixtures of carbon dioxide and chloroform. According to P. Schützenberger, carbonyl chloride is formed when a mixture of carbon dioxide and carbon tetrachloride is passed through a red-hot tube packed with pumice-stone: $\text{CO}_2 + \text{CCl}_4 = 2\text{CO} + \text{Cl}_2$. J. Dewar studied the condensation phenomena with mixtures of carbon dioxide and carbon tetrachloride, and with methyl chloride. As previously indicated, a mixture of carbon dioxide and carbon disulphide when passed through a hot tube furnishes carbonyl sulphide. The conditions were studied by W. Hempel. The reaction was also studied by A. Deniger. When the mixed gases are passed over heated copper, A. Eiolart observed a reaction represented by: $\text{CO}_2 + \text{CS}_2 + 4\text{Cu} = 2\text{CO} + 2\text{Cu}_2\text{S}$. M. Thilorier said that liquid carbon dioxide and disulphide are miscible in all proportions. L. P. Cailletet said the miscibility extends only over a limited range. J. Dewar found at 19° carbon dioxide liquefies in the presence of carbon disulphide at 49 atm. press.; at 35°, at 78 atm.; at 40°, at 85 atm.; and at 58°, at 110 atm. press. The liquid carbon dioxide then floats on the surface of the disulphide; at 47° and 80 atm., the layers of liquid are not so well marked; at 110 atm., the upper liquid almost wholly disappeared, and on reducing the press. to 80 atm. the liquids were completely mixed. A reduction of 5 atm. in the press. caused the liquid again to separate into layers. J. A. Wanklyn found that acetic acid is formed when carbon dioxide reacts with sodium methyl, and propionic acid, with sodium ethyl. Numerous other reactions of carbon dioxide with organic compounds have been reported by K. Brunner, etc. For the action of carbon dioxides on the carbonates, *vide* the metal hydrocarbonates. G. Gore observed no separation of carbon when the vapour of ammonium carbonate and carbon dioxide are passed through a red-hot tube. L. Naudin and F. de Montholon said that dry carbon dioxide has no action on dried potassium cyanide; but in the presence of water, hydrocyanic acid and potassium carbonate are slowly formed. When carbon dioxide is passed over heated potassium thiocyanate, J. Milbauer found that sulphur, carbonyl sulphide, carbon monoxide, and potassium cyanate are formed: $\text{KCN} = \text{KCN} + \text{S}$; $\text{KCN} + \text{CO}_2 = \text{CO} + \text{KCNO}$, or $\text{KCNS} + \text{CO}_2 = \text{KCNO} + \text{COS}$; and $\text{COS} = \text{CO} + \text{S}$. G. Gigli found that a soln. of potassium ferrocyanide, sat. with carbon dioxide gave some hydrocyanic acid when distilled, and a greenish product, probably potassium ferrous ferrocyanide, $\text{K}_2\text{Fe}(\text{FeC}_6)$, was formed. The reaction is not essentially different from that between sulphuric acid and potassium ferrocyanide. J. Matuschek represented the reaction by: $2\text{K}_4\text{FeC}_6 + 4\text{CO}_2 + 4\text{H}_2\text{O} + \text{O} = 2\text{Fe}(\text{OH})_3 + 4\text{K}_2\text{CO}_3 + 12\text{HCy}$; and with potassium ferricyanide, $2\text{K}_3\text{FeC}_6 + 3\text{CO}_2 + 9\text{H}_2\text{O} = 2\text{Fe}(\text{OH})_3 + 3\text{K}_2\text{CO}_3 + 12\text{HCy}$. In both cases the potassium carbonate and hydrocyanic acid react giving ammonia and formic acid. C. L. Carey studied the absorption of carbon dioxide by gels of agar-agar, gelatine, and starch.

G. Gore¹⁰ found that silicon does not decompose carbon dioxide in the presence of water, and that a mixture of silicon tetrafluoride and carbon dioxide is not changed when passed through a red-hot tube. L. Dovéri, C. Struckmann, A. Johnstone, C. Döbelts, W. P. Headdon, G. G. C. Bischof, W. R. and R. E. Rogers, H. St. C. Deville, T. Dietrich, A. Cossa, A. Pavesi and E. Rotondi, R. J. Müller, etc., have studied the action of carbon dioxide or aq. soln. of carbon dioxide on silica or silicate rocks—*vide* the silicates. H. Herbst found the gas is not adsorbed by silicic acid. R. Bunsen studied the action on glass of water charged with carbon dioxide under press. L. Pfandler believed that a chemical action occurs, for, when a strong light is projected upon a glass tube filled with compressed carbon dioxide near its critical point, the surface of the glass above the level of the liquefied gas is found to be corroded as though with hydrofluoric acid. It is thus not improbable that a chemical action, effected within a few minutes under the influence

of a strong press. and intense light, can proceed slowly, under a slight press. and ordinary daylight. H. Weil, and B. von Szyszkowsky found that **ultramarine** in contact with soln. of sodium chloride charged with carbon dioxide gives off hydrogen sulphide; and P. N. Raikow found that ultramarine is not changed after it has been in contact with carbon dioxide for many hours. D. Gerasimoff studied the action of carbon dioxide on **alkali titanates**. H. Herbst found carbon dioxide is not adsorbed by wad, dried wood, paraffin, or sugar.

F. Briegleb and A. Geuther¹¹ observed that carbon dioxide reacts with heated **magnesium nitride**, producing cyanogen, carbon, and carbon monoxide. F. Wöhler found that when a mixture of dried **ammonia** and carbon dioxide is moderately heated, ammonium carbamate, $\text{NH}_2\text{COONH}_4$, and at a higher temp., carbamide, $\text{CO}(\text{NH}_2)_2$, and ammonium carbamate are formed; but, added R. E. Hughes and F. Soddy, if the two gases are thoroughly dried no reaction occurs. E. C. C. Baly and co-workers studied the photosynthesis of naturally occurring nitrogen compounds from carbon dioxide and ammonia. E. Rengade found with **sodioammonium**, NaNH_2 , below -50° , sodium carbamate, NH_2COONa , is produced. Similarly also with **potassioammonium**, KNH_2 . At a rather higher temp., -10° to -5° with potassioammonium, and -35° to -25° with sodioammonium, hydrogen is liberated and the alkali formates are produced. F. Beilstein and A. Geuther observed that with **sodium amide**, NaNH_2 , dried carbon dioxide forms cyanamide. The reaction has been studied by W. P. Winter, and E. Drechsel; according to the latter, the reaction progresses in stages: $\text{NaNH}_2 + \text{CO}_2 \rightarrow \text{NH}_2\text{COONa}$; $\text{NH}_2\text{COONa} - \text{H}_2\text{O} + \text{NaCNO}$; and $\text{NaCNO} + \text{NaNH}_2 \rightarrow \text{H}_2\text{O} + \text{Na}_2\text{CN}_2$. J. Dewar found that carbon dioxide and **nitrous oxide**, when liquefied, mix together in all proportions; and on reducing the press., one liquid evaporates before the other, and gives a distinct line of separation. R. B. Moore liberated nitrogen oxide from soln. of **potassium nitrite**, **sodium nitrite**, and **silver nitrite** by carbon dioxide. E. R. Marle obtained a similar result with a soln. of potassium nitrite. D. Huizinga stated that carbon dioxide liberates nitrous acid from **ammonium nitrite**, but, added E. von Gorup-Besanez, only if a trace of hydrochloric acid is present. L. Meunier said that carbon dioxide does not liberate nitrous acid from sodium nitrite, but C. Marie and R. Marquis claim that this is wrong because (i) Purified carbon dioxide was passed into a soln. of sodium nitrite containing potassium iodide and starch paste; the development of a blue colour indicated the liberation of iodine by nitrous acid; (ii) A soln. of potassium iodide and sodium nitrite produced no coloration in chloroform, whilst a similar soln. sat. with carbon dioxide caused the chloroform to become violet; (iii) A soln. of potassium iodide and starch was coloured blue by carbon dioxide which had previously passed through a soln. of sodium nitrite; and (iv) an aq. soln. of β -naphthylamine and sulphanic acid, which gives an orange-red colour with even traces of nitrous acid, gives the same reaction when carbon dioxide is passed into a soln. of sodium nitrite.

According to A. R. Leeds,¹² moist **phosphorus** does not reduce carbon dioxide to the monoxide, but it forms phosphine. J. H. Niemann found that liquid carbon dioxide is not affected by phosphorus. According to L. P. Cailletet and M. Bordet, when a mixture of equal vols. of phosphine and carbon dioxide is compressed in the presence of water a white crystalline body is formed without any gaseous residue; the solid is a mixture of phosphonium hydroxide, and hydrated carbon dioxide; and it is not formed above 22° . M. Berthelot said that when a mixture of **phosphine** and carbon dioxide is passed through a tube at dull redness, there is no evidence of the formation of hydrocarbons, and at a bright red heat, carbon monoxide and hydrogen are formed; while G. Gore said that no carbon is produced under these conditions. T. E. Thorpe and A. E. Tutton found that carbon dioxide does not act on **phosphorus trioxide** either at ordinary temp. or when heated. According to J. Dewar, when a mixture of carbon dioxide and **phosphorus trichloride** is compressed at 16.2° and 42.95 atm. or at 23° and 46.91 atm., the gases liquefy—the carbon dioxide condenses first, and the liquids mix together in a few minutes. At

30° and 49·9% atm. the carbon dioxide is less soluble in the liquid phosphorus trichloride than at lower temp. According to A. Barillé, dry carbon dioxide does not act on dry calcium phosphate. He found that the metal phosphates in contact with water under press. behave like calcium phosphate and form carbonatophosphates (vide 3, 24, 30)—e.g. the phosphates of the alkalies and alkaline earths, ammonium, and magnesium. These all form hydrocarbonates. The other phosphates simply dissolve in the carbonic acid without decomposition. F. K. Cameron and A. Seidell said that the presence of carbon dioxide does not affect the action of water on calcium hydrophosphate, but it raises the quantity of dissolved phosphoric acid in the case of calcium dihydrophosphate, and normal calcium phosphate. J. Davy said that water sat. with carbon dioxide under press. dissolves normal calcium phosphate rather more than does water alone—vide calcium phosphates. E. Shepherd observed no reduction of carbon dioxide to the monoxide when in the presence of ferrous phosphate and exposed to light. E. N. Horsford, however, said that a mixture of carbon dioxide, in the presence of water, sodium phosphate, and ferrous sulphate, is reduced to carbon monoxide in light or in darkness. H. Struve has also studied the reaction. L. J. Henderson and O. F. Black studied the equilibrium conditions between carbon dioxide, sodium hydrocarbonate, hydrophosphate, and dihydrophosphate. D. Gerasimoff investigated the action of carbon dioxide on the alkali vanadates, tantalates, and columbates.

According to R. Lorenz,¹³ boron at a red heat reduces carbon dioxide to boron trioxide and carbon. L. C. Jones found that an excess of carbon dioxide in contact with the borates can slowly displace the boric acid. J. Davy observed no difference in the action of water sat. with carbon dioxide under press. and of water alone on alumina. D. Gerasimoff studied the action of carbon dioxide on the alkali aluminates, and tungstates. E. Schweizer showed that carbon dioxide converts potassium chromate in aq. soln. into potassium dichromate and carbonate. The reaction was studied by P. Sabatier, F. Mohr, etc. A. Bach's observations on the action of carbon dioxide on soln. of uranium salts have been discussed in connection with the action of light on carbon dioxide and water. The reaction has also been investigated by H. Euler, F. L. Uffler and J. H. Priestley, E. Mameli and G. Pollacci, A. J. Ewart, etc.

¹⁴ H. Davy, and J. L. Gay Lussac and L. J. Thénard found that when heated with potassium or sodium, carbon dioxide is reduced to carbon, and some alkali carbonate is formed. E. Drechsel said that sodium, mixed with some calcined quartz sand, absorbs dried carbon dioxide at 260° and forms some sodium oxalate; similar results were obtained with a 2 per cent. sodium amalgam. H. Kolbe and R. Schmidt found that if kept in a warm moist atm. of carbon dioxide for 24 hrs., potassium is converted into a mixture of potassium hydrocarbonate and formate: $2K + 2CO_2 + H_2O = KHCO_3 + H.COOK$; M. Ballo gives $2H_2CO_3 + 2K = KHCO_3 + H.COOK + H_2O$. H. Kolbe and R. Schmidt added that the yield of formate with sodium is less than with potassium. A. Lieben found that 0·5 to 3·0 per cent. potassium and sodium amalgams, or barium amalgam with aq. soln. of carbon dioxide, furnish a mixed soln. of hydrocarbonate and formate. Light had no influence on the result. Alcoholic soln. behave similarly. Small quantities are also formed if phosphoric or sulphuric acid be present, but the amount of formic acid produced decreases with increasing proportions of the mineral acid. C. Kippenberger, and A. Bach also obtained formic acid by the action of the alkali amalgams on carbonic acid. H. Moissan found that calcium at a dull red heat reduces carbon dioxide, forming calcium oxide and carbon. G. Gore said that potassium and sodium are not affected by liquid carbon dioxide. M. Thilorier stated that liquid carbon dioxide is decomposed by potassium, and L. P. Cailletet added that liquid carbon dioxide is not reduced by sodium or sodium amalgam, but that some sodium hydrocarbonate is formed owing to the presence of a trace of moisture in the liquid. H. Limpricht stated that at a dark red heat copper reduces carbon dioxide to the monoxide; but A. Perrot observed no reduction either at a bright red heat or at a

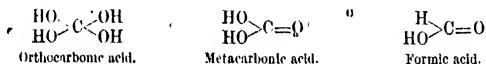

Full red heat when purified copper was used; reduction occurred if the copper contained a trace of iron or zinc; while, according to A. Schrötter, copper decomposes carbon dioxide at a bright red heat only when hydrogen is present. E. Lautemann, O. L. Erdmann, and G. Neumann have made observations on this subject. According to M. Thilorier, copper is not affected by liquid carbon dioxide.

S. Parkinson found that magnesium at a red heat burns with incandescence in carbon dioxide and carbon is formed. F. Kessler isolated the carbon by washing the product of the reaction with dil. nitric acid. C. Winkler said that much of the carbon reacts with the carbon dioxide forming carbon monoxide, which is therefore a secondary product of the reaction. H. R. Ellis found that the amorphous carbon contains much graphite. The reaction has also been discussed by V. Wartha, H. Cretier, and T. L. Phipson. According to K. Brunner, magnesium powder burns on solid carbon dioxide producing a grey cake which, when treated with dil. hydrochloric acid, leaves black flecks of carbon. According to M. Ballo, S. Kappel, and G. Giorgis, magnesium dissolves in a soln. of carbonic acid with the evolution of hydrogen and the formation of magnesium carbonate which dissolves as hydrocarbonate in the excess of the soln. A. Lieben found that a little formic acid is produced by the action of an aq. soln. of carbonic acid on magnesium with or without the addition of traces of acid; H. J. H. Fenton obtained formaldehyde as a result of this reaction, and the yield was considerably increased in the presence of feeble bases—like ammonia, aluminium hydroxide, aniline, etc. A. Lieben obtained formic acid as a result of treating an aq. soln. of carbonic acid with magnesium in the presence of sodium phosphate, ammonium carbonate, or potassium sulphate, and baryta-water; he also found that zinc reacts with carbonic acid like magnesium, and that platinized zinc does not reduce carbon dioxide either in alkaline or ammoniacal soln. According to M. Thilorier, zinc is not affected by liquid carbon dioxide. H. Jahn found that moist carbon dioxide is reduced to the dioxide when heated with zinc-dust. N. T. de Saussure said that in the presence of mercury the passage of electric sparks through carbon dioxide produces mercuric oxide with the separation of carbon. W. von Bolton found that mercury vapour in the presence of moisture separates some carbon from carbon dioxide. J. D. van der Plaats studied the vaporization and surface tension of mercury in an atm. of carbon dioxide. N. Wender found that moist carbon dioxide at a high press. has but a very slight action on aluminium. A. Guntz and A. Masson found that, as a rule, finely powdered aluminium is only slightly affected when heated in carbon dioxide, but the commercial powder often becomes incandescent under these conditions, and some aluminium carbide is formed. If a trace of aluminium chloride or iodide is present, the conversion to carbide is more or less complete. A. Lieben found that aluminium behaves like magnesium towards carbonic acid, and with aluminium amalgam in the presence of alkali salts, small quantities of formates are produced. K. Brunner found that aluminium powder burns on solid carbon dioxide and gives a dense graphitic carbon. A. Guntz found that finely divided manganese burns in carbon dioxide, forming manganese oxide; E. Müller and H. Barck showed that some manganese carbide is also formed at 800°. The solubility of lead in water is decreased by carbonic acid. The subject has been investigated by G. Flögel, M. Müller, F. Clowes, E. Reichardt, C. Guldensteeden-Egeling, G. A. Barbaglia and P. Gucci, S. Buzicka, G. von Knorre, etc.—*vide* lead. According to M. Thilorier, lead is not affected by liquid carbon dioxide. N. T. de Saussure observed that when iron is heated in carbon dioxide, ferrous and ferric oxides are formed and carbon is produced. G. Tissandier also noted the formation of carbon monoxide. J. B. A. Dumas, and J. Braithwaite made some observations on this subject; and P. Sabatier and J. B. Senderens said that carbon dioxide is not perceptibly reduced by iron between 330° and 450°. M. Thilorier said iron is not affected by liquid carbon dioxide. According to G. Besseyre, hydrogen is given off in the action of carbon dioxide and water on iron, if air be excluded, and ferrous carbonate passes into soln. If the excess of carbon dioxide be removed and air has access, ferric hydroxide separates

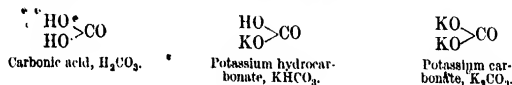

from the soln. C. von Hauer, O. Kröhnke, P. Petit, and J. Rothe and F. W. Hinrichsen have studied this subject—*vide* iron. I. L. Bell noted that carbon dioxide is soon reduced by finely divided **nickel** at a dull red heat; and, added P. Sabatier and J. B. Senderens, no appreciable reduction occurs between 230° and 400°. I. Langmuir observed no spluttering of **platinum**, or **platinum-rhodium**; wires in carbon dioxide at 1300°, but with the latter it began at 1400°. F. Erlich found that the spluttering of **iridium** in carbon dioxide increases with the rise of temp., and this more rapidly than in a mixture of oxygen and nitrogen; and he suggested that the action involves the oxidation and deoxidation of iridium, $4\text{CO}_2 + \text{Ir} \rightleftharpoons \text{IrO}_4 + 4\text{CO}$.

Carbon dioxide reacts with many of the **metal oxides** and **hydroxides**, forming carbonates—*e.g.* the oxides or hydroxides of the alkalis and alkaline earths. F. K. Cameron and W. O. Robinson¹⁵ studied the action on metal hydroxides of carbon dioxide under press. at 0°. Red-hot **stannous oxide** was found by A. Wagner, to reduce carbon dioxide to the monoxide; and when a mixture of ferrous chloride and sodium carbonate is heated to redness in a stream of carbon dioxide, some carbon monoxide is formed. L. Gruner found that **ferrous oxide** is transformed into ferrosferrie oxide when heated in a stream of carbon dioxide, but there is no separation of carbon. F. Forster studied the action of carbon dioxide on **lead oxide**. According to W. F. Channing, enough heat is developed by solid **potassium** and **sodium hydroxides** in contact with solid carbon dioxide, to inflame gun-cotton; there is no rise of temp. with **barium**, **strontium**, and **calcium oxides**, but there is with the corresponding hydroxides. No perceptible heating occurs with **lead**, **zinc**, and **copper oxides**, but there is a slight heating effect with the hydroxides. E. Gilchrist investigated the use of solid sodium hydroxide as an absorbent for carbon dioxide in mine rescue apparatus. R. Dubrisay studied the neutralization of carbonic acid by sodium hydroxide. According to L. P. Cailletet, liquid carbon dioxide reacts with **potassium carbonate**, forming a complex which remains in soln. possibly as **potassium pyrocarbonate**, $\text{K}_2\text{CO}_3\text{CO}_2$.

With our present knowledge two carbonic acids appear possible. **Ortho-carbonic acid** corresponding with $\text{C}(\text{OH})_4$, or H_4CO_4 , is not known, although some **orthocarbonates** are known—*e.g.* ethyl orthocarbonate, $\text{C}(\text{OC}_2\text{H}_5)_4$, was prepared by H. Bassett.¹⁶ E. Wilke considers it probable that aq. soln. of carbon dioxide contain orthocarbonic acid. The ordinary carbonates are really **metacarbonates** derived from **metacarbonic acid**, $\text{CO}(\text{OH})_2$, so that metacarbonic acid is the first dehydration product of orthocarbonic acid. The so-called **formic acid** may be regarded as a derivative of metacarbonic acid made by replacing one hydroxyl group by hydrogen;

Metacarbonic acid is a weak dibasic acid, and it furnishes a series of **hydrocarbonates** in which the group HCO_2 acts as a monad radicle, and a series of normal **carbonates** in which the group CO_3 acts as a dyad radicle. The constitutions of carbonic acid and each of these types of salts are usually represented:

The metacarbonates also furnish some complex salts. The individual carbonates are discussed in connection with the metals. J. F. Armand discussed the general problem as early as 1804. The carbonates are all decomposed by treatment with the mineral acids, although the native carbonates of magnesium—magnesite, and dolomite—and of iron—siderite—do not effervesce with the cold mineral acids;

but if the carbonate be powdered or the acid be warmed, dissolution readily occurs, and carbon dioxide is evolved. The carbonates of the alkali earths are sparingly soluble in water, and when an aq. soln. of a hydroxide of one of these earths is exposed to the action of carbon dioxide, the soln. becomes turbid and a voluminous precipitate of the carbonate is formed in the cold. The precipitate soon becomes compact and crystalline when the liquid is warmed. Lime-water or baryta-water is therefore used in the detection of carbon dioxide. If a small quantity of a carbonate is being tested, the mixture is warmed to drive the carbon dioxide into the reagent; and a non-volatile acid—sulphuric or phosphoric acid—is used for the decomposition of the carbonate so as to avoid a volatile acid being carried along with the carbon dioxide, and preventing the formation of a precipitate. According to J. L. Lassaigne, baryta-water is rendered turbid by a soln. of sodium carbonate containing one part of carbon dioxide in between 40,000 and 80,000 parts of water; and a sensible precipitation occurs with lime-water when the proportion of water does not exceed 20,000 parts of water to one of carbon dioxide. According to J. J. Welter, and C. L. Berthollet, lime-water actually dissolves a little carbonate, so that the lime-water employed for the qualitative test should be digested for some time with calcium carbonate. If an excess of carbon dioxide be passed through the soln. of lime-water, the precipitate redissolves, and the liquid becomes clear. This is due to the formation of soluble calcium hydrocarbonate: $\text{CaCO}_3 + \text{CO}_2 + \text{H}_2\text{O} = \text{Ca}(\text{HCO}_3)_2$. If this soln. be boiled, the hydrocarbonate is decomposed, the carbon dioxide escapes, and the calcium carbonate is reprecipitated. Similarly, if lime-water be added to the soln. of the hydrocarbonate calcium carbonate is precipitated, $\text{Ca}(\text{HCO}_3)_2 + \text{Ca}(\text{OH})_2 = 2\text{CaCO}_3 + 2\text{H}_2\text{O}$.

Unlike sodium carbonate, sodium hydrocarbonate does not give a precipitate with magnesium sulphate, and hence G. Patein recommended this reaction as a distinguishing test for hydrocarbonate and carbonate. M. von Pettenkofer detected free carbonic acid in the presence of hydrocarbonates by means of a soln. of one part of rosolic acid in 500 parts of 85 per cent. alcohol, and adding baryta-water until it begins to acquire a red tinge. 0.5 c.c. of this soln. will remain red if no free carbonic acid be present, and it will become colourless or faintly yellow if free carbonic acid is present. According to F. M. Perkin, carbon dioxide and hydrocarbonates liberate hypochlorous acid from soln. of hypochlorites. On adding a soln. of the substance to be tested to a mixed soln. of potassium bromide and bleaching powder, bromine is at once liberated should the substance be a hydrocarbonate, and may be dissolved by shaking with 2 c.c. of chloroform. Normal carbonates have no action. T. Salzer recommended using Nessler's reagent (4. 31, 26) as a test for free carbonic acid or hydrocarbonates, because if these substances are present, the ammonia reaction does not occur. According to L. Dobbin, the reagent can also be used to detect fixed alkali hydroxides in the presence of the fixed alkali carbonates, for the former alone give a brown precipitate. The test is not reliable in the presence of sulphides. The great avidity of sodium hydroxide for carbon dioxide may be illustrated by several ingenious experiments. One of the simplest is to collect a cylinder of carbon dioxide over mercury and then pipette some sodium hydroxide soln. under the edge of the cylinder. The sodium hydroxide rises to the top of the mercury, absorbs the gas, and the mercury rises in the cylinder accordingly. Potassium hydroxide is better suited as an absorbent for carbon dioxide than sodium hydroxide, because when a gas charged with carbon dioxide is bubbled through a wash-bottle the exit may become choked with solid sodium hydrocarbonate; the sodium hydrocarbonate is less soluble in water than potassium hydrocarbonate. Soln. of sodium hydroxide are largely employed in analytical work as absorbents for carbon dioxide. If air charged with carbon dioxide be drawn through a soln. of sodium hydroxide in a weighed wash-bottle, the increase in weight represents the weight of carbon dioxide absorbed by the hydroxide. If the vol. of the air be known, the amount of carbon dioxide in that vol. of air follows at once. Similarly in gas analysis, the amount of carbon dioxide is

determined from the contraction in vol. which a given vol. of the gas suffers after the gas has been in contact with sodium hydroxide.

The carbon dioxide in carbonates can be determined gravimetrically by the loss in weight consequent on the evolution of the gas displaced by an acid. Something approaching three hundred portable instruments have been described for this purpose. The gas is absorbed by alkali-lye as indicated above and weighed, or the gas can be absorbed by a standard soln. of baryta-water, the remaining baryta-water can then be titrated with a standard soln. of an acid using phenolphthalein as indicator. This enables the amount of baryta carbonated to be computed, and hence the quantity of carbon dioxide absorbed. This process was devised by M. von Pettenkofer in 1857. O. Warburg showed that warm soln. of barium hydroxide absorb carbon dioxide far more rapidly than cold soln.

Physiological action of carbon dioxide.—Atmospheric air contains 0.03 per cent. of carbon dioxide, and the air of crowded halls may have as much as 0.5 per cent. without causing any appreciable effect. According to L. Hill,¹⁷ when the proportion rises to 3 per cent., the breathing becomes deeper and faster, and the pulse becomes fuller and faster; 4 per cent. produces unpleasant panting, and diminishes the power to work; 6 to 7 per cent. causes distressful panting; 10 per cent. produces violent panting, throbbing of the arteries, and flushing of the face; and 25 per cent. may cause death in animals after exposure for several hours. The respiration of dangerous mixtures of carbon dioxide and air are attended by a feeling of heaviness, giddiness, noises in the ear, tightness across the chest, and an inclination to sleep. The muscles then lose their power, and the individual if standing falls to the ground. There then follow asphyxia, coma, stertorous breathing, cyanosis—possibly convulsions and delirium—and death may ensue if the victim be not rescued.

According to J. S. Haldane and co-workers, the air *within the lungs* normally contains about 5.6 per cent. of carbon dioxide; when this reaches about 8 per cent. dizziness and loss of memory occur, with higher percentages there may be loss of consciousness, but no immediate danger until the proportion exceeds 20 to 30 per cent. Recovery is rapid and complete. L. Hill found that diving under water, or holding the breath as long as possible, may raise the carbon dioxide in the air in the lungs to 7 to 10 per cent. A temporary rise of 3 per cent. is thus quite a natural phenomenon. The organism may acquire a certain tolerance for the gas and breathe the air contaminated with an amount of carbon dioxide which would be noxious to the untrained organism. J. S. Haldane and co-workers showed that the oxygenation of the blood helps to drive off the carbon dioxide, while the deoxygenation of the blood helps the absorption of carbon dioxide so that the exhalation of carbon dioxide by the lungs is to a large extent dependent on the taking up of oxygen.

Poisoning by carbon dioxide is probably a misnomer in that the lethal effects are due to a deficiency of oxygen rather than to an excess of carbon dioxide. Carbon dioxide asphyxia may occur in coal mines from the presence of choke damp generated by explosions and gob fires; in deep wells, cellars, excavations, and underground passages; in brewer's vats; and in the neighbourhood of lime-kilns and brick-kilns in operation.

The equilibrium between carbonic acid and bicarbonates in the regulation of the reactions of blood has been discussed by H. Friedenthal, and L. J. Henderson, K. A. Hasselbalch and C. Lundsgaard found that the H⁺-ion conc. of blood is about $0.044N$, and is subject to slight variations, decreasing as the blood passes through the lungs and increasing during the greater circulation. K. Spiro and L. J. Henderson have discussed the change of distribution of the red blood corpuscles and plasma as the tension of the carbonic acid changes:

As the blood passes through the tissues it receives carbonic acid, and the vol. of the red corpuscles increases owing to the entry of water from the plasma; chlorine simultaneously passes in the same direction; and other changes occur. In the lungs with the escape of carbon dioxide, the process is reversed. In each complete cycle of the circulation, there

occurs a complete cycle of changes between the constituents of the corpuscles and the plasma.

¹ The effect of carbon dioxide on micro-organisms has been discussed by C. Nourry and C. Michel,¹⁸ etc.; on fermentation by L. Lindet,¹⁹ G. Foth, etc.; and on plant seeds by P. Becquerel, S. Jentys, etc.

² **The uses of carbon dioxide.**—Carbon dioxide²⁰ is largely used in the preparation of the so-called artificial mineral waters; and for impregnating beers, wines, etc. Carbon dioxide is used²¹ in the manufacture of carbonated beverages, where it improves the appearance, and imparts to them sparkle and "life." It is said to have a marked stimulating effect on the olfactory and gustatory nerves, accentuating flavours, and making the senses more delicately perceptive. It also has a bactericidal action in keeping down the bacterial counts of carbonated beverages. The gas is used in packing certain food products where flavours and odours are liable to be spoiled—presumably owing to the oxidation of certain constituents, if packed in air. It has also been recommended in the storage of fruits. Carbon dioxide is substituted for air in the atm. of the freezer in some systems of making ice-cream. It is used in manufacturing various carbonates—e.g. white lead, barium carbonate, sodium hydrocarbonate, etc.; in the ammonia-soda and the cryolite processes for alkali carbonates; and in the precipitation of aluminium hydroxide in one process for the purification of bauxite. Liquid carbon dioxide is used as a refrigerating agent, and it has several advantages over ammonia and sulphur dioxide. There are many other applications—liquid carbon dioxide has been used for hardening steel, extinguishing fires, raising sunken ships, etc. Carbon dioxide is used in sugar works for removing lime from the limed sugar-cane juice. Liquefied carbon dioxide in cylinders is used as a decentralized source of press. over 500 lbs. per sq. in. Carbon dioxide is used as a fire extinguisher in closed spaces where it acts by excluding oxygen from burning bodies; or by diluting the air. It is used as a mild irritant and stimulant on the respiratory centres; for local refrigeration; and as a cauterant. It is used in the rubber industry for filling the air-bags which support tyres in the process of vulcanizing. It has been recommended for removing extremely hard and adherent boiler scale.

§ 37. Hard and Soft Water

Water comes very near to the "universal solvent" of the alchemists' dreams. Natural water holds carbon dioxide in soln., and when such water comes in contact with magnesium and limestone rocks, some may be dissolved.¹ Water holding magnesium and calcium salts in soln. is said to be **hard**. The term is applied on account of the difficulty of obtaining a soap-lather with such water. Soap is a compound of sodium with a fatty acid. The soap is decomposed by magnesium

or calcium salts. The fatty acid unites with the latter to form an insoluble curdy precipitate. This action continues until all the lime and magnesian salts have been precipitated. Any further addition of soap at once produces a lather, and the soap can then be used as a cleansing agent. If a soln. of soap of definite strength and a definite vol. of water be employed, the hardness of a given sample of water can be represented in terms of the amount of soap required to produce a lather. The hardness of water thus refers to the "soap-destroying power" of the water, and it is expressed in degrees. Each degree of hardness corresponds with one grain of calcium carbonate, or its equivalent in other calcium or magnesium salts, per gallon of water. Hardness is also expressed in parts of calcium carbonate, or its eq., per 100,000 parts of water. Waters containing but small quantities of lime and magnesian salts lather freely with soap, and they are accordingly called **soft waters**. A water less than 5° hardness may be called "soft," and a water between 18° and 20° hardness is "moderately hard," and if over 30° hardness, "very hard." Very soft waters are liable to attack metals like lead, zinc, and iron.

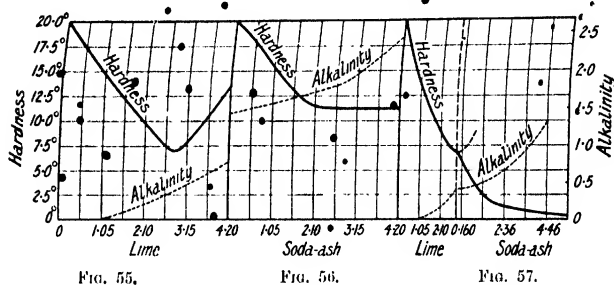

The process of removing salts from hard water is called **softening the water**. In **T. Clark's lime process for softening water** the necessary amount of milk of lime or lime-water is added to convert all the acid carbonates of calcium and magnesium into the normal carbonates. We have here the curious paradox—"add lime to remove lime." The theory of the action is summarized in the equation: $\text{Ca}(\text{HCO}_3)_2 + \text{Ca}(\text{OH})_2 = 2\text{CaCO}_3 + 2\text{H}_2\text{O}$. M. R. Herrie and F. M. Gleeson showed that in the progressive addition of lime-water to hard water, the hardness decreases uniformly so long as the chemical action between the lime and the salts in the water takes place. When this action is complete, the water is at its minimum hardness (7°, Fig. 55), and any further addition of lime-water increases the hardness and the alkalinity of the water. Expressing the amount of lime added to the water in lbs. of lime per 1000 galls. of hard water; the hardness in c.c. of standard soap soln.; and the alkalinity in c.c. of 0.04N-acid with phenolphthalein as indicator, the results with a natural water of 20° hardness were:

Lime . . .	0.0	0.52	1.57	2.62	2.91	3.14	4.20	5.25
Hardness . .	20.0°	17.5°	12.5°	7.5°	7.0°	7.5°	13.5°	19.5°
Alkalinity . .	0	0	0.8	0.30	0.36	0.43	0.75	1.13

Hard water may be wholly or partially softened by boiling. That part of the hardness so removed is termed temporary hardness; the degree of hardness which remains after prolonged boiling is called **permanent hardness**. Temporary hardness is due to calcium and magnesium hydrocarbonates; permanent hardness is due to the presence of calcium and magnesium chlorides or sulphates. There is also a kind of "pseudo-hardness" due to the insolubility of soap in water containing sodium chloride. The so-called *marine soaps* are used for such waters. After removing the temporary hardness, if present, by boiling or by T. Clark's lime-process, the permanent hardness may be removed by the addition of sodium carbonate—the **soda process**. The sodium carbonate precipitates the calcium and magnesium as insoluble carbonates: $\text{CaSO}_4 + \text{Na}_2\text{CO}_3 = \text{CaCO}_3 + \text{Na}_2\text{SO}_4$. The water still contains sodium sulphate and sodium chloride, but the presence of a small quantity of these salts is not usually objectionable. M. R. Herrie and F. M. Gleeson showed that with the progressive addition of soda-ash the hardness of water rapidly diminishes to a minimum (11°, Fig. 56), and the chemical action between the soda-ash and the salts of the hard water is complete. Further additions of soda-ash produce no change on the hardness, but merely increase the alkalinity. Expressing the hardness and alkalinity as before, but expressing the amount of soda-ash added as lbs. of soda-ash per 1000 galls. of hard water, the results with a natural water were:

Soda-ash . .	0.0	0.52	1.05	1.57	2.10	2.62	3.14	3.66	4.20
Hardness . .	—	16°	15.5°	13°	11.5°	11°	11°	11°	11°
Alkalinity . .	1.45	1.55	1.65	1.70	1.75	1.85	2.00	2.25	2.45

It follows, therefore, that the addition of lime to hard water produced a minimum hardness of 7° by precipitating some of the soluble salts producing hardness due to calcium and magnesium; the other salts of these elements still in soln. are removed by soda-ash but not by lime; similarly, the addition of soda-ash produced a minimum hardness of 11° by precipitating some of the salts producing hardness due to calcium and magnesium; the other salts of these elements still in soln. are removed by the addition of lime but not by soda-ash. By adding both reagents in proper proportions—the so-called **soda-lime process**—nearly all the salts producing hardness are removed. This is illustrated by Fig. 56.

FIGS. 55-57. Changes of Hardness and Alkalinity of Natural Water with Additions of Lime, and Soda-ash Separately and Consecutively.

The processes used for softening potable hard water may thus be summarized: (1) Distillation; (2) Boiling; (3) The addition of lime with or without soda-ash or other chemicals; and (4) The permutite process—*vide* alkali aluminosilicates. The Report of the Rivers Pollution Commission classified unpolluted water as is shown in Table XXVI, which represents the average of a number of analyses of each type.

TABLE XXVI. AVERAGE COMPOSITION OF UNPOLLUTED NATURAL WATERS

Class of water.	Total solids.	Organic carbon.	Organic nitrogen.	Ammonia.	Nitrogen (nitrates and nitrites).	Total combined nitrogen.	Chlorine.	Hardness.		
								Temporary.	Permanent.	Total.
Rain	2.95	0.070	0.015	0.029	0.003	0.042	0.822	0.4	0.5	0.9
Upland surface	9.67	0.322	0.032	0.002	0.009	0.042	1.130	1.5	4.3	5.8

Spring	28.20	0.056	0.013	0.001	0.383	0.396	2.49	11.0	7.5	18.5

Boiler scale.—The furring of kettles, and the formation of boiler scale, is due to the precipitation of calcium and magnesium salts. Boiler scale is a poor conductor of heat, and hence the efficiency of a boiler which has scaled is seriously impaired. The boiler scale and the metal have different rates of contraction and expansion by heat. If the water in the boiler gets low, and the metal overheated, the scale may separate from the metal. If cold water now runs into the boiler, the scale quickly cools, contracts, and cracks. Water pours through the cracks on to the hot metal; a large volume of steam is generated, and the sudden pressure may be great enough to burst the boiler. Hard water in steam boilers not only produces boiler scale, but it may corrode the boiler shell, and cause foaming and bumping. The corrosion

and pitting of boilers is usually produced by soft waters from swampy districts which contain organic acids in soln.; by water from mining districts containing mineral acids in soln. (e.g. sulphuric acid from the oxidation of pyrites); and by water containing magnesium or calcium chlorides and nitrates. A great many nostrums for preventing boiler scale and corrosion have been proposed. In some, the water is treated before it enters the boiler; in others, the water is softened in the boiler itself. Whatever agents be used, they must be cheap; easily applied; yield no acid when used; and precipitate the salts which make the water hard in a flocculent powdery condition easily blown from the boiler. Among the commoner agents are: sodium or calcium hydroxide, and sodium carbonate discussed above; sodium aluminate, NaAlO_2 , which acts as represented by the equation: $2\text{NaAlO}_2 + \text{Ca}(\text{HCO}_3)_2 + 2\text{H}_2\text{O} = \text{Na}_2\text{CO}_3 + 2\text{Al}(\text{OH})_3 + \text{CaCO}_3$; sodium fluoride which acts: $2\text{NaF} + \text{Ca}(\text{HCO}_3)_2 = 2\text{NaHCO}_3 + \text{CaF}_2$; normal sodium phosphate which acts: $2\text{Na}_3\text{PO}_4 + 3\text{CaSO}_4 = 3\text{Na}_2\text{SO}_4 + \text{Ca}_3(\text{PO}_4)_2$; etc.

There are numerous works specially dealing with the purification of water for boiler and domestic purposes; e.g. S. and E. Rideal, *Water Supplies, Their Purification, Filtration, and Sterilization*, London, 1914; J. Don and J. Chisholm, *Modern Methods of Water Purification*, London, 1913; W. W. Christie, *Water: Its Purification and Use in the Industries*, London, 1912; W. P. Booth, *Water Softening and Treatment*, London, 1920; F. Fischer, *Das Wasser*, Leipzig, 1914.

Hard water in nature.—Water highly charged with dissolved calcium bicarbonate may be dripping through the roof of a cave or subterranean cavern. Some carbon dioxide escapes from the soln., and a certain amount of calcium carbonate is deposited. Each drop adds its own little share of calcium carbonate. The deposit grows—maybe on the roof, when it is called a stalactite; maybe on the floor, when it is called a stalagmite. All depends upon the time occupied by each drop in gathering and dropping. The stalagmite grows upwards from the ground, and the stalactite grows downwards, like an icicle, from the roof. In time, the two may meet and form a pillar. Fig. 58 conveys but little idea of the beauty of some limestone

FIG. 58.—Stalactites and Stalagmites in the Yarrangobilly Caves, N.S.W.

caverns in which stalactites and stalagmites have been growing. The photograph shows stalactites, stalagmites, and pillars which have no doubt been formed in this manner. The San Filippo spring (Tuscany) is said to deposit lime at the rate of 12 inches a month, and the spring has formed a bed of limestone rock 250 feet thick, $1\frac{1}{2}$ miles long, and $\frac{1}{2}$ mile wide. The building stone called travertine (Tiberstone) is probably a limestone deposited from a mineral spring. The Colosseum and much of ancient and modern Rome were built with this stone.

§ 38. Percarbonic Acid and the Percarbonates

Die Natur einiger Percarbonate ist heute noch nicht einwandfrei geklärt.—C. F. VON GIRSEWALD.

Guided by analogy with the persulphates, E. J. Constan and A. von Hansen¹ sought to prepare a series of percarbonates. They assumed that the ionization of the normal carbonates takes place in stages, and that when conc. soln. are electrolyzed, the ions MCO_3' formed in the first stage of the ionization will accumulate in the anode compartment, and there unite to form a percarbonate, $2\text{MCO}_3' + 2\oplus = \text{M}_2\text{C}_2\text{O}_6$, as in the analogous case of the persulphates, $2\text{MSO}_4' + 2\oplus = \text{M}_2\text{S}_2\text{O}_8$. It was necessary to work at low temp., but under that condition sodium and ammonium carbonates have too small a solubility, and the soln. are too dil. to give the desired result. The experiment, however, was successful with potassium and rubidium carbonates. When a sat. aq. soln. of potassium carbonate is electrolyzed and the temp. continuously diminished, the anodic evolution of oxygen becomes less and less, and at -10° has practically ceased; simultaneously a bluish solid, potassium percarbonate, is formed. There is generally a marked odour of ozone at the beginning of the electrolysis, but this disappears in a short time.

W. D. Brown thus applied E. J. Constan and A. von Hansen's process: A porous cell of 200 c.c. capacity was placed in a cylindrical vessel of such size that the outer or anode space had a capacity of 150 c.c. In the porous cell was the cathode of nickel gauze and the cathode soln. of 20-40 per cent. potassium carbonate. Around the porous cell, in the conc. soln. of potassium carbonate, a platinum wire was wound as a spiral. The whole was immersed in a mixture of ice and common salt, which brought the temp. down to -15° . A conc. soln. of potassium carbonate, at 15° , has a sp. gr. of 1.556. On lowering the temp. of this soln., no crystallization takes place; but if the salt be impure, or if crystallization takes place on lowering the temp., then, on passing a current, no crystals of potassium percarbonate are formed. It is necessary to have a high anode density and a low cathode density. This was attained by having the nickel gauze cathode and platinum wire anode. The wire was 0.0345 cm. thick and 48 cms. long, making an anode surface of 0.05 sq. dm. With a current of 3 amps. at about 10 volts, and a current density of about 60 amps. per sq. dm., the soln. was heated too much and potassium hydrocarbonate was formed. On shortening the anode wire to 24 cms., and passing a current of 14 amps., the current density remained the same, and a mass of blue crystals of the percarbonate, floating on the anode soln., was obtained. E. J. Constan and A. von Hansen found that if the electrolysis is commenced at -15° , with a conc. soln., the yield is not much affected by small variations of temp.—indeed, the temp. may rise to 0° without seriously impairing the yield. If the conc. of the electrolyte falls below sp. gr. 1.52, a rise in temp. diminishes the yield. It is preferable gradually to lower the temp. as the electrolysis proceeds, owing to the decrease in the conc. of the soln. The percarbonate is very soluble in water, and to get a deposition of solid percarbonate it is necessary to keep the anode liquor sat. with respect to potassium carbonate. This is done by continuously running through a funnel a conc. soln. of potassium carbonate to the bottom of the anode compartment, and allowing the lighter electrolyzed liquor to overflow. This liquor carries the suspended solid percarbonate which is then collected on a vacuum filter. At -10° with a soln. of sp. gr. 1.56, a yield of 25.55 per cent. of percarbonate was obtained with a current density of 0.5-2.0 amps. per sq. dm.; but when the current density rose to 60 amps. per sq. dm., the yield rose to 85-95 per cent. F. Salzer found that the yield was considerably diminished by platinizing the anode, for this increases the surface and decreases the current density; the potential of a smooth anode is greater than that of a platinized one. Iron, nickel, copper, and silver anodes were found by A. von Hansen to be unsatisfactory. F. Salzer found that the presence of hydroxyl ions or of hydr

arbonates diminished the yield. The sky-blue, hygroscopic potassium percarbonate so prepared is dried by spreading it on a porous plate and exposing it to a current of air; the temp. may be raised to 40° towards the end of the drying. The product contains 87-93 per cent. of percarbonate. A. von Hansen said that the product cannot be purified by recrystallization from water, but it may be purified by digestion with an excess of a conc. soln. of potassium hydroxide at -5° to -10° for some time; the percarbonate is then washed with alcohol to remove the hydroxide, and the dried product has 95 to 99 per cent. of percarbonate. E. H. Riesefeld and B. Reinhold claim to have made a 100 per cent. product by the electrolysis of a conc. soln. of potassium carbonate containing 82.5 grms. of $K_2CO_3 \cdot 2H_2O$ per 100 grms. of water at -30° to -40°. P. Lami has also described the electrolytic preparation of this salt.

According to E. J. Constan and A. von Hansen, potassium percarbonate is a hygroscopic sky-blue powder, which, when dried, loses almost all its colour and appears white. Analyses correspond with the composition $K_2C_2O_6$. The dry salt is fairly stable; there is a slow decomposition: $4K_2C_2O_6 = 4K_2CO_3 + 4CO_2 + 2O_2$, but if moist it soon decomposes: $2K_2C_2O_6 + 2H_2O = 4KHCO_3 + O_2$. When gently warmed the salt decomposes: $2K_2C_2O_6 = 2K_2CO_3 + 2CO_2 + O_2$, but the reaction is completed only above 200°. The salt dissolves in ice-cold water almost without decomposition, but at ordinary temp.—particularly between 45° and 50°—it decomposes with the evolution of oxygen. It is assumed that the first action is the resolution of the percarbonate into hydrogen dioxide and hydrogencarbonate: $K_2C_2O_6 + 2H_2O = 2KHCO_3 + H_2O_2$, so that the oxygen is derived from the decomposition of the hydrogen dioxide in alkaline soln. The rate of decomposition of the ammonium salt furnished W. Biltz and W. Gahl constants in agreement with a unimolecular reaction, although other methods of calculation corresponded with a bimolecular reaction. The value of the constant changes with the conc. of the soln. The mechanism of the reaction, like that with ammonium nitrite, has not been established. The salt is but sparingly soluble in alcohol. With dil. sulphuric acid there is a quantitative yield of hydrogen dioxide: $K_2C_2O_6 + H_2SO_4 = K_2SO_4 + 2CO_2 + H_2O_2$. The acid soln. bleaches potassium permanganate: $5K_2C_2O_6 + 8H_2SO_4 + 2KMnO_4 = 2MnSO_4 + 6K_2SO_4 + 8H_2O + 10CO_2 + 5O_2$. The strength of potassium percarbonate as an oxidizing agent can thus be determined by titration with a standard sulphuric acid soln. of permanganate. A dil. aq. soln. of potassium hydroxide, even at -2°, forms potassium carbonate and hydrogen dioxide: $K_2C_2O_6 + 2KOH = 2K_2CO_3 + H_2O_2$. The hydrogen dioxide rapidly decomposes in the alkaline soln. For a conc. aq. soln. of potassium hydroxide, *vide supra*. The oxidizing properties of potassium percarbonate are illustrated by its converting lead sulphide to the sulphate, ferrous to ferric salts, and stannous to stannic salts; decolorizing indigo-blue, and bleaching cotton, silk, wool. The reducing properties of the salt are illustrated by its action on silver oxide, manganese dioxide, and lead dioxide, when the carbonates of the respective metals are formed, and oxygen is evolved—e.g. $K_2C_2O_6 + PbO_2 = PbCO_3 + K_2CO_3 + O_2$. It can be regarded as **potassium perdicarbonate**, and is probably constituted:

In general, said F. P. Treadwell, potassium percarbonate in aq. soln. behaves like hydrogen dioxide. Sodium dioxide acts more quickly than potassium percarbonate on chromium sulphate; the former with manganese sulphate gives a brown precipitate of manganese dioxide, while the latter gives a small quantity of the brown precipitate, but much manganese carbonate which is immediately converted to the brown dioxide when sodium hydroxide is added. The percarbonate liberates iodine from hydriodic acid. According to E. H. Riesefeld and B. Reinhold, when a solid percarbonate is added to a conc. neutral soln. of potassium iodide, iodine is immediately set free. This is taken to show that hydrogen dioxide has not been formed because that compound liberates iodine very slowly from potassium iodide; if, however, a soln. of the percarbonate be used instead of the solid salt, the amount of iodine set free decreases with the length of time the soln. of percarbonate has

been kept before it was added to the potassium iodide. This is because the salt in soln. is gradually decomposed into potassium hydrocarbonate and hydrogen dioxide. There has been a controversy between E. H. Riesenfeld and B. Reinhold, S. M. Tanatar, and R. Wolfenstein as to the validity of potassium iodide as a test for distinguishing the percarbonates from carbonates containing hydrogen dioxide of crystallization. R. Willstätter, and E. H. Riesenfeld and W. Mau so distinguished the persulphates from sulphates with hydrogen dioxide of crystallization, and it is inferred that the analogous reaction is valid with the carbonates. A. Monnier found that percarbonates give a reddish precipitate with a dil. soln. of titanous chloride; no precipitation or coloration with a 0.5 per cent. alcoholic soln. of benzidine; and a blue coloration with a soln. of potassium dichromate acidified with sulphuric acid—*vide* perborates.

E. J. Constan and A. von Hansen prepared rubidium percarbonate, $Rb_2C_2O_6$, in a manner analogous to the potassium salt; the properties of the two salts were similar. They did not succeed in obtaining the solid sodium percarbonate and ammonium percarbonate, although these salts were probably present in soln. Similar remarks apply to E. H. Riesenfeld and B. Reinhold's attempt to isolate the corresponding lithium percarbonate, sodium percarbonate, rubidium perdicarbonate, and cesium perdicarbonate. L. Schwedes prepared sodium percarbonate by passing carbon dioxide into a paste made of sodium dioxide and alcohol. The residue appears as a white flocculent mass with 50 per cent. of the percarbonate. H. Wade treated sodium carbonate with hydrogen dioxide in presence of a limited quantity of water and of sodium chloride for salting out the product. The use of calcined sodium carbonate is advantageous, and so is the presence of negative catalysts—sodium silicate or magnesium chloride—as shown by F. Noll. P. Kasanezky dissolved 5 grms. of freshly prepared ammonium carbonate in 40 c.c. of 20 per cent. hydrogen peroxide, and the soln., after cooling in ice, was mixed with 5 c.c. of aq. ammonia sat. at 0°. The addition to the liquid of 2-3 vols. of alcohol then gave a white, crystalline precipitate of a salt having the constitution $NH_4O.O.CO.O.NH_4, 2H_2O$. The salt is readily soluble in water, by which it is almost completely decomposed into hydrogen peroxide and ammonium carbonate. W. Biltz and W. Gahl found that the decomposition of ammonium percarbonate may be represented as a unimolecular reaction.

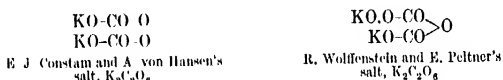

In 1899, S. M. Tanatar found that when a soln. of sodium carbonate is dissolved in cold 3 per cent. hydrogen peroxide, and the soln. treated with alcohol, a white crystalline precipitate is obtained. After washing with alcohol and ether, and drying over sulphuric acid, the product has the composition $Na_2CO_3, 1\frac{1}{2}H_2O$, or the alternative $Na_2CO_3, H_2O_2, \frac{1}{2}H_2O$. Against the latter formula, S. M. Tanatar urged (i) that the heat of decomposition of a 1, *N*-soln. by 1, *N*-nitric acid is 7.21 to 7.26 Cals., whereas that of an aq. soln. of sodium carbonate is 5.33 Cals.; and (ii) that the partition coeff. of hydrogen dioxide between ether and aq. soln. of sodium carbonate shows that the carbonate unites with 30 per cent. of the hydrogen dioxide. The argument, however, is inconclusive in distinguishing between a percarbonate and a compound of sodium carbonate and hydrogen dioxide. E. H. Riesenfeld and W. Mau showed that (i) ether will not extract hydrogen dioxide from E. J. Constan and A. von Hansen's salt, but it will do so from S. M. Tanatar's salt; and (ii) there is no liberation of iodine when the latter salt is added to a neutral soln. of potassium iodide. It is therefore inferred that S. M. Tanatar's salt is not a true percarbonate, but is rather hemihydrated sodium perhydroxycarbonate $Na_2CO_3, H_2O_2, \frac{1}{2}H_2O$. When the salt is heated over 100° it gives off oxygen and water, but no carbon dioxide. It dissolves in water with the absorption of 3.9 Cals., and the aq. soln. forms hydrogen dioxide and sodium carbonate. With acids, it yields carbon dioxide and hydrogen dioxide; but with hydrochloric and hydriodic acids the halogens are set free. Salts of the alkaline earths and the metals give unstable precipitates which develop oxygen and form carbonates. S. M. Tanatar made sodium sesquiperhydroxycarbonate, $Na_2CO_3, 1\frac{1}{2}H_2O_2$, using twice as much hydrogen dioxide as he employed

in making the salt $\text{Na}_2\text{CO}_3 \cdot \text{H}_2\text{O}_2 \cdot \frac{1}{2}\text{H}_2\text{O}$. He symbolized it $\text{Na}_2\text{CO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}_2 \cdot \text{H}_2\text{O}$. The two salts are alike in appearance and properties. S. M. Tanatar made the potassium salt $\text{K}_2\text{CO}_4 \cdot 3\text{H}_2\text{O}$ in a similar way. The product was contaminated with a little potassium carbonate, and is probably dihydrated **potassium perhydroxycarbonate**, $\text{K}_2\text{CO}_3 \cdot \text{H}_2\text{O}_2 \cdot 2\text{H}_2\text{O}$. P. Kasanezky obtained hemihydrated **potassium diperhydroxycarbonate**, $\text{K}_2\text{CO}_3 \cdot 2\text{H}_2\text{O}_2 \cdot \frac{1}{2}\text{H}_2\text{O}$, by mixing one molar proportion of potassium carbonate with five molar proportions of 25 per cent. hydrogen dioxide, or by mixing potassium hydrocarbonate with a tenfold excess of 30 per cent. hydrogen dioxide, and precipitating the salt with alcohol. The product consists of rhombic prisms mixed with monoclinic prisms. It is resolved into potassium carbonate and hydrogen dioxide when dissolved in water. P. Kasanezky also made **potassium triperhydroxycarbonate**, $\text{K}_2\text{CO}_3 \cdot 3\text{H}_2\text{O}_2$, by adding 7.5 c.c. of 25 per cent. hydrogen dioxide to a gram of the preceding salt, and treating the product with alcohol. The salt dissolves in water with the evolution of oxygen. E. Peltner prepared **rubidium triperhydroxycarbonate**, $\text{Rb}_2\text{CO}_3 \cdot 3\text{H}_2\text{O}_2$, or $\text{Rb}_2\text{CO}_4 \cdot 2\text{H}_2\text{O}_2 \cdot \text{H}_2\text{O}$; hydrated **rubidium diperhydroxycarbonate**, $\text{Rb}_2\text{CO}_3 \cdot 2\text{H}_2\text{O}_2 \cdot \frac{1}{2}\text{H}_2\text{O}$, or $\text{Rb}_2\text{CO}_4 \cdot \text{H}_2\text{O}_2 \cdot 2\text{H}_2\text{O}$; and sesquihydrated **rubidium perhydroxycarbonate**, $\text{Rb}_2\text{CO}_3 \cdot \text{H}_2\text{O}_2 \cdot \frac{1}{2}\text{H}_2\text{O}$, or $\text{Rb}_2\text{CO}_4 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, by dissolving one molar proportion of rubidium carbonate in one, two, or three molar proportions of 30 per cent. hydrogen dioxide soln., and sufficient water to obtain a clear soln. on adding alcohol to the cooled soln., these substances are precipitated in the form of white, crystalline solids; they are all very hygroscopic, and evolve oxygen on being dried in a vacuum, but if kept dry they do not turn yellow. The dried substances evolve more oxygen on moistening with water. P. Kasanezky dissolved 5 grms. of freshly-prepared ammonium carbonate in 40 c.c. of 20 per cent. hydrogen dioxide, and, after cooling in ice, mixed the soln. with 5 c.c. of aq. ammonia sat. at 0°. The addition to the liquid of 2-3 vols. of alcohol then gave a white, crystalline precipitate of hydrated **ammonium perhydroxycarbonate**, $(\text{NH}_4)_2\text{CO}_3 \cdot \text{H}_2\text{O}_2 \cdot \text{H}_2\text{O}$, which he regarded as having the constitution $(\text{NH}_4)_2\text{CO}_4 \cdot 2\text{H}_2\text{O}$, or $(\text{NH}_4\text{O})_2\text{CO}_2 \cdot 2\text{H}_2\text{O}$. The salt is readily soluble in water, by which it is decomposed into ammonium carbonate and hydrogen dioxide.

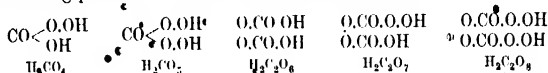

R. Wolfenstein and E. Peltner prepared a number of percarbonates by the action of carbon dioxide on sodium dioxide or on sodium hydroperoxide obtained by the action of a mol of sodium ethoxide on $\frac{1}{2}$ mol of hydrogen dioxide, and washing the precipitate with alcohol. It is claimed that the products are true percarbonates, and not merely carbonates with hydrogen dioxide of crystallization. The first product sesquihydrated **sodium permonocarbonate**, $\text{Na}_2\text{CO}_4 \cdot 1\frac{1}{2}\text{H}_2\text{O}$, is obtained by triturating in a dish cooled by a freezing mixture, 38 grms. of sodium dioxide with 50 grms. of ice, and then passing a slow current of carbon dioxide through the mixture while it is being stirred. The mass becomes mushy as water is split off, and 38 grms. more sodium dioxide are added in small portions at a time. The current of gas is stopped when the increase in weight is 44 grms., or, according to E. H. Riesenfeld and W. Mau, when a sample of the liquor requires twice as much hydrochloric acid for neutralization with methyl orange as indicator as it does with phenolphthalein as indicator. The unstable salt is washed with alcohol and ether, and dried in vacuo. The salt slowly loses oxygen in the desiccator, and decomposition is complete in a couple of months. If 18.75 grms. of freshly prepared sodium hydroperoxide are mixed with 5.2 grms. of water and the mixture cooled by a freezing mixture while it is treated with carbon dioxide until the increase in weight is 6.8 grms., a salt is obtained whose composition corresponds with $\text{Na}_2\text{C}_2\text{O}_6 \cdot \text{H}_2\text{O}$. According to E. H. Riesenfeld and W. Mau, it is doubtful, however, if this formulation is correct. Its behaviour towards a neutral soln. of potassium iodide is related with that of Na_2CO_3 as that of $\text{Na}_2\text{C}_2\text{O}_6 \cdot \text{H}_2\text{O}_2$ is related with that of $\text{Na}_2\text{C}_2\text{O}_6$. Hence, the salt is regarded as **sodium perhydroxypermonocarbonate**, $\text{Na}_2\text{CO}_4 \cdot \text{H}_2\text{O}_2$. By analogy with the formula of permonosulphuric acid, $\text{HO} \cdot \text{SO}_2 \cdot \text{O} \cdot \text{OH}$, the constitutional formula of the permonocarbonate is given as $\text{NaO} \cdot \text{O} \cdot (\text{CO}) \cdot \text{O} \cdot \text{Na}$. H. Bauer,

and E. Merck have described analogous processes for making the percarbonates. F. Noll emphasized the importance of removing metal compounds present as impurities which act catalytically in decomposing the per-salt. E. Merck prepared **barium permonocarbonate**, $\text{BaCO}_4 \cdot n\text{H}_2\text{O}$, by the action of carbon dioxide on **hydrated barium dioxide**. R. Wolfenstein and E. Peltner prepared the salt in a similar way. Neither alcohol nor ether extracts hydrogen dioxide, and it is therefore not considered to be constituted $\text{BaCO}_3 \cdot \text{H}_2\text{O}_2$.

According to R. Wolfenstein and E. Peltner, **sodium perdicarbonate**, $\text{Na}_2\text{C}_2\text{O}_6$, is obtained by mixing 2 to 3 grms. of sodium dioxide with 100 c.c. of ice-cold absolute alcohol, and passing carbon dioxide into the well-stirred mixture, at 0° to 5° , for 5 or 6 hrs. or until the soln. no longer reacts alkaline towards phenolphthalein. The mass of glistening crystals is washed with alcohol and ether, and dried in air for a short time on a porous plate. The analyses corresponded with $\text{Na}_2\text{C}_2\text{O}_6 \cdot \frac{1}{2}(\text{C}_2\text{H}_5\text{O})_2$ and, if moist sodium dioxide is used to absorb the carbon dioxide, the crystals obtained have the composition $\text{Na}_2\text{C}_2\text{O}_6 \cdot \frac{1}{2}\text{H}_2\text{O}$. Again, if 5 c.c. of 30 per cent. hydrogen dioxide are added to the mixture before the treatment with carbon dioxide, or stirred with the mixture after the absorption of carbon dioxide is complete, crystals are obtained corresponding with NaHCO_4 . E. H. Riesenfeld and W. Mau showed that the behaviour of the salt towards a neutral soln. of potassium iodide corresponds with the assumption that the product is **sodium perhydroxyperdicarbonate**, $\text{Na}_2(\text{C}_2\text{O}_6 \cdot \text{H}_2\text{O}_2)$. They also prepared **potassium perdicarbonate**, $\text{K}_2\text{C}_2\text{O}_6$, by the above process using potassium dioxide, absolute alcohol, and carbon dioxide. This salt has the same empirical composition as the salt obtained by E. J. Constan and A. von Hansen. The two compounds in soln. or in the solid state react differently towards a neutral soln. of potassium iodide, and they are therefore isomers. The supposed constitutional difference is illustrated by the formulae:

The following percarbonic acids are oxidized carbonic acids:

as well as the derivatives $\text{HO}-\text{CO}-\text{O}-\text{CO}-\text{O}-\text{OH}$, etc. The alkali salts of $\text{H}_2\text{C}_2\text{O}_4$ and of $\text{H}_2\text{C}_2\text{O}_6$ in its two isomeric forms have been prepared. The alleged derivatives of $\text{H}_2\text{C}_2\text{O}_5$ —namely, $\text{Na}_2\text{C}_2\text{O}_5 \cdot \text{H}_2\text{O}$ —and of $\text{H}_2\text{C}_2\text{O}_7$ —namely, $\text{Na}_2\text{C}_2\text{O}_7 \cdot \text{H}_2\text{O}$ —are probably salts of the lower oxidized percarbolic acids with hydrogen dioxide of crystallization. The simpler problems connected with the percarbonates are not definitely settled. Even the evidence on which the distinction between percarbonates and addition compounds of hydrogen dioxide and the normal carbonates is based, is inconclusive. Free **percarbonic acid** has not been isolated. A. Bach claimed that it can exist in ethereal soln. at a low temp., for if a soln. of 0.5 gm. of solid phosphoric acid, ether, and a few drops of water are added to 2 grms. of potassium percarbonate, there is a violent reaction. When the ethereal soln. is poured off, and treated with an alcoholic soln. of potassium hydroxide, a bluish-white precipitate of potassium percarbonate is formed. This is taken to show that the ether held percarbonic acid in soln. R. Wolfenstein and E. Peltner, however, deny the alleged facts.

The above terminology is based on that usually employed for the persulphates; E. H. Riesenfeld and W. Mau suggested calling the derivatives of $\text{H}_2\text{C}_2\text{O}_4$, *monoperoxy carbonates*, and those of $\text{H}_2\text{C}_2\text{O}_6$, *monoperoxydicarbonates*. R. Wolfenstein and E. Peltner called $\text{Na}_2\text{C}_2\text{O}_6$, *sodium dioxide dicarbonate*; $\text{Na}_2\text{C}_2\text{O}_7$, *sodium trioxide dicarbonate*, etc.

Potassium percarbonate is used in photography under the name *antihypo* for removing the last traces of sodium thiosulphate; it has been recommended for bleaching purposes; and for oxidations in some analytical processes. Sodium permonocarbonate has been used for medical purposes, as a disinfectant, and in the preparation of hydrogen dioxide.

§ 39. The Sulphides of Carbon

A number of carbon sulphides has been reported: (i) *Carbon disulphide*, CS_2 , is the best defined sulphide; (ii) The existence of a gaseous *carbon monosulphide*, CS , and of its polymerized forms, C_nS_n , appears highly probable. The evidence of the existence of (iii) *carbon ditritasulphide*, C_3S_2 , and of its polymerized forms is not so satisfactory; and there is some doubt about the existence of (iv) *carbon sesquisulphide*, or *carbon trihemisulphide*, C_2S_3 ; (v) *carbon tetrilasulphide*, C_4S ; and of (vi) *carbon dipentilasulphide*, C_5S_2 , as chemical individuals.

O. Loew¹ claimed to have made *carbon tetrilasulphide*, or *carbon quadrantsulphide*, C_4S , by distilling phosphorous sulphide with acetic acid, and extracting the soluble matters with carbon disulphide. It is said to decompose when heated; to be soluble in conc. sulphuric acid; and to be attacked vigorously by warm nitric acid. A similar sulphide was mentioned by F. Clément and J. Dôsmornes, and J. J. Berzelius. L. Rauh claimed to have made *carbon dipentilasulphide*, C_5S_2 , by the action of sodium on carbon disulphide. The brownish-red product is soluble in alkali-lye and ammonia, but not in carbon disulphide, alcohol, or ether. It is said to be fusible at 135° , and decomposable at 150° . O. Loew reported the formation of *carbon sesquisulphide* or *carbon trihemisulphide*, C_2S_3 , by digesting the product of the action of phosphorous sulphide on acetic acid, or of sodium or sodium amalgam on carbon disulphide, with conc. aq. ammonia, and passing chlorine into the soln.—keeping the ammonia in excess. The product was purified by digesting it with sodium sulphite, washing with hot water, and with alcohol, and finally drying. The brown powder has no smell; it is decomposed into its constituents first over 110° . It is slightly soluble in carbon disulphide; and is scarcely attacked by ammonia. A boiling soln. of baryta water or potash-lye forms the metal sulphide and oxalate. Nitric acid oxidizes it to an acid which forms an easily soluble barium salt, and sparingly soluble lead and silver salts. C. Löwig gave the acid the formula $(\text{CS})_2\text{O}_2\text{H}_2\text{O}$, or $(\text{COS})_2$ —possibly thio-oxalic acid. The individuality of these three carbon sulphides has not been definitely established, and they may be impure polymerides of carbon monosulphide. J. P. Wibaut and A. Stoffel attribute the sulphur in coke and coal to the presence of carbon sulphides which do not decompose at 1000° . They say that in coking, the sulphur of the pyrites is liberated and unites with the carbon, forming compounds stable at this temp. J. P. Wibaut made such sulphides with 2.03 and 3.5 per cent. of sulphur by heating sugar-charcoal and sulphur at 400° – 1000° under reduced press.

B. von Lengyel prepared carbon dinitrasulphide, C_3S_2 , by boiling purified and dried carbon disulphide in a reflux apparatus while the vapour is exposed to an electric arc maintained between two carbon poles for two or three hours, the interior of the apparatus becomes blackened, and a black substance is found suspended in the liquid. If this is filtered off, a cherry-red liquid is obtained, which has a remarkably strong odour, and produces great irritation of the eyes. This liquid is allowed to stand for 6-8 days over metallic copper to remove free sulphur, and is then evaporated by means of a current of dry air. A deep red liquid is thus left which has the composition C_3S_2 . A. Stock and P. Prätorius prepared the compound by passing carbon disulphide through a heated quartz tube, the most favourable temp. being 1000° - 1100° ; carbon is deposited in the tube at the same time, and diminishes the yield of dinitrasulphide. If the quartz tube is filled with a spiral of iron wire, the formation of dinitrasulphide takes place below 800° , but it soon ceases owing to the formation of iron sulphide. They also found that the compound is formed, along with many by-products, when an arc is struck between carbon or metal electrodes; under liquid carbon disulphide the disintegration of the anode exposes fresh, hot surfaces continually to the carbon disulphide. Iron, copper, and aluminium electrodes gave no dinitrasulphide, whilst electrodes of arsenic, bismuth, lead, tin, antimony, cadmium, or zinc yielded the required compound, large quantities of the metallic sulphides being formed at the same time. The best results were obtained with a carbon cathode and an anode consisting of antimony mixed with 7 per cent. of carbon. The brownish-red soln. obtained is filtered, and then shaken with mercury and phosphoric oxide to remove sulphur and polysulphides and water. A soln. of carbon dinitrasulphide in carbon disulphide is thus obtained, from which by distillation, finally under a high vacuum, the pure substance is obtained in a receiver cooled to -40° as a yellowish-red solid.

Carbon dinitrasulphide at ordinary temp. forms a bright red strongly refracting liquid; B. von Lengyel found that it evaporates in the air very slowly, and its vapour has a most vigorous action on the mucous membrane, a very small trace causing violent catarrh. Placed on the skin, it merely produces a black spot. The sp. gr. of the liquid is 1.27389. According to A. Stock and P. Prätorius, the m.p. is -0.5° . The vap. density corresponds with the formula $(C_3S_2)_2$; so also does the mol. wt. in carbon disulphide; and, according to B. von Lengyel, the mol. wt. by the f.p. method in benzene soln. A. Stock and P. Prätorius consider carbon dinitrasulphide to be the anhydride of thiomalonic acid, since, when treated with aniline, it readily forms thiomalonanilide. Hence its constitution is, represented $S : C : C : C : S$. This sulphide is therefore analogous with carbon dinitroxide (*q.v.*). When heated, the dinitrasulphide is converted into a hard, black mass with the same percentage composition, and which is probably a polymeride. When the liquid is rapidly heated to 100° - 120° , this change takes place with explosive violence, but occurs gradually when it is gently warmed. A. Stock and P. Prätorius found that the polymerization at 90° is a reaction of the second order, and has been observed by measuring the diminution of press. The reaction occurs on the surface of the containing vessel. B. von Lengyel observed that the polymeride is formed when the liquid is preserved for a few weeks, and its formation is in all cases accompanied by the production of a little carbon disulphide. The liquid can be distilled under diminished press. at 60° - 70° , but a portion of it is always converted into the solid modification. The liquid substance is insoluble in water, in which it sinks, but is readily soluble in alcohol, ether, chloroform, benzene, and carbon disulphide. From a conc. soln. in the solvent last mentioned, the solid modification is deposited, but a dil. soln. is more stable. According to A. Stock and P. Prätorius, the alcoholic soln. decomposes after a short time. Dil. soln. in carbon disulphide are salmon-coloured, more conc. soln., yellowish-brown; above 1 per cent. conc. the soln. gradually deposit black, polymerization products, even in the dark; soln. below 1 per cent. conc. are stable in the dark, but not in the sunlight. Carbon disulphide soln. have no action on copper or mercury, but are decomposed by the sulphides

of these metals, owing, probably, to the formation of additive products. B. von Lengyel found that the ditritasulphide burns with a luminous, smoky flame, carbon and sulphur dioxides being formed. Aq. potassium and sodium hydroxides give almost black soln., in which acids produce black precipitates, whilst alcoholic potash acts vigorously and yields a deep brown soln. A drop of conc. sulphuric acid causes violent hissing, and the whole mass is converted into the solid modification. Conc. nitric acid causes ignition, whilst a more dil. acid dissolves the liquid, neither carbon dioxide nor sulphuric acid being formed. The solid modification is hard, has a fine, granular fracture, and is insoluble in water and all ordinary solvents. Aq. potassium hydroxide dissolves it completely, and it appears to be precipitated unaltered on the addition of an acid. When heated, it decomposes, with the formation of sulphur, which sublimes, and a gas which contains sulphur, but is not carbon disulphide. A. Stock and P. Prätorius found that the black polymerization product is not affected by water, sodium hydroxide, hydrochloric acid, or chlorine water. Heated in a vacuum it gives carbon disulphide and a black residue which still contains 39 per cent. of sulphur. When bromine is added to a soln. of the liquid tricarbon disulphide in chloroform, heat is evolved, and a yellow precipitate produced; this is carbon disulphohexabromide, $C_3S_2Br_6$, which has an aromatic odour, and is insoluble, or only very slightly soluble, in all solvents. Under similar conditions, a yellow precipitate is produced with chlorine, but not with iodine.

There has been a number of reports of the preparation of the sulphur analogue of carbon monoxide, CO, namely carbon monosulphide, CS. In 1857, for example, A. Baudrimont claimed to have made this compound as a colourless gas smelling like ether, (i) by passing the vap. of carbon disulphide over red-hot pumice-stone, or platinum sponge; (ii) by decomposing the same compound by heating it to redness with carbon or hydrogen; (iii) by heating antimony sulphide with an excess of carbon; (iv) by the action of carbon monoxide on hydrogen sulphide at a high temp.; (v) by the action of sulphur dioxide or chloride on methane at a high temp.; and (vi) by the action of heat on sulphur cyanide. J. F. Persoz claimed that he had prepared this compound twenty years earlier than A. Baudrimont. M. Berthelot, L. Playfair, and A. Husemann showed that A. Baudrimont's observations are probably wrong. H. Buff and A. W. Hofmann did not obtain the alleged compound by the action of an electrically heated spiral, nor did A. W. Hofmann obtain it by the action of induction sparks on the vap. of carbon disulphide; and B. Rathke did not obtain the monosulphide by passing the vapour of thiocarbonyl chloride, $CSCl_2$, over heated copper.

O. Loew stated that the gradual decomposition of carbon disulphide, exposed to direct sunlight, is attended by the separation of solid carbon hemitrisulphide, C_2S_3 , and the excess sulphur remains dissolved in the carbon disulphide. T. Skot found that carbon monosulphide is formed when carbon disulphide is exposed to sunlight. The deposit on the walls of the vessel was washed with carbon disulphide. It is a red powder of sp. gr. 1.65; without taste or smell; and is insoluble in water, alcohol, turpentine, or benzene. It colours dil. nitric acid red and is inflamed by the conc. acid. A boiling conc. soln. of potassium hydroxide dissolves it, forming a dark brown soln. from which the monosulphide is precipitated by adding an excess of acid. The monosulphide decomposes at 200° into carbon and sulphur, and when heated with sulphur, it forms carbon disulphide and colourless crystals which were not investigated. According to J. Dewar and H. O. Jones, the product obtained by T. Sidot was a polymerized form of carbon monosulphide. S. Kern claimed to have made carbon monosulphide by allowing the disulphide to stand for a long time in contact with iron wire; iron disulphide is simultaneously formed. S. M. Losnitsch and M. Z. Jovitschitsch found that when carbon disulphide is decomposed by the silent electric discharge in the presence of hydrogen or carbon monoxide, what is supposed to be carbon monosulphide is formed: $CS_2 + H_2 = H_2S + CS$, and $CS_2 + CO = COS + CS$. J. Thomsen said that when nitrogen sat. with the vap. of

carbon disulphide is passed repeatedly over heated copper, the copper removes some sulphur from the carbon disulphide, leaving carbon monosulphide.

J. Dewar and H. O. Jones found that thiocarbonyl chloride reacts rapidly at ordinary temp. with nickel carbonyl (*q.v.*): $n\text{CSCl}_2 + n\text{Ni}(\text{CO})_4 = n\text{NiCl}_2 + 4n\text{CO} + (\text{CS})_n$. The nickel chloride can be extracted by water, and a brown solid remains. The analyses agree with $(\text{CS})_n$. The reaction takes place, although less rapidly, at -20° , and the same result is obtained when the reacting substances are dissolved in dry ether, light petroleum, carbon tetrachloride, or chloroform. Even when the reacting liquids are carefully dried over phosphoric oxide, the carbon monosulphide is still obtained. The purification of the substance is rendered difficult by the fact that it retains water and thiocarbonyl chloride with great persistence. To remove these as far as possible, the product obtained after extracting with water, was dried at 100° , and then at 150° or 200° , under reduced press. The finely divided substance had a sp. gr. of about 1.6; after compression into a solid block, the value 1.83 was obtained. The mol. vol. is therefore 24, which is about 10 per cent. greater than the sum of the at. vol. of its constituents. Carbon monosulphide is not altered by dil. sulphuric acid, but with the conc. acid it gives a purplish-brown soln., the colour of which is slowly destroyed at the b.p. when carbon dioxide and sulphur dioxide are evolved. When the purplish-brown soln. is poured into water, unchanged carbon monosulphide is precipitated. It is dissolved by conc. nitric acid at the ordinary temp., giving a red soln. the colour of which is only slowly destroyed on heating. It dissolves in aq. or alcoholic soln. of ammonia, ammonium sulphide, and potassium hydroxide, sulphide and hydrosulphide, giving deep brown soln., from which acids precipitate the carbon monosulphide unchanged. When heated in a good vacuum, no change takes place below 360° , except the liberation of a small quantity of hydrogen sulphide; at a low, red heat, carbon disulphide is formed according to $2(\text{CS})_n = x\text{C} + x(\text{S}_2)$. When heated in a current of dry hydrogen, hydrogen sulphide is evolved; when heated in dry chlorine, sulphur is evolved. Owing to its non-volatility, it seems probable that the red substance obtained by long exposure of carbon disulphide to sunlight is also a polymeric form of carbon monosulphide.

According to A. Deninger, gaseous carbon monosulphide is formed when sodium sulphide is heated with chloroform at 180° , and when silver sulphide is heated with iodoform. It is best obtained, mixed with hydrogen, by bringing 15 grms. of sodium into 125 c.c. of dry aniline, and adding 150 c.c. of carbon disulphide. A gas is given off which is passed through aq. soda, over india-rubber, and, finally, through triethylphosphine. It has the composition of carbon monosulphide; it readily burns with a blue flame, forming sulphurous anhydride. The gas is very readily absorbed by alcohol and aniline, has a pleasant smell of purified carbon disulphide, and condenses in a freezing mixture to a very volatile liquid, the constants of which have not been determined. When mixed with oxygen and ignited, it explodes violently. J. Dewar and H. O. Jones also found that when carbon disulphide vap. at low press. is subjected to the action of the silent discharge, in an ozonizer, it appears to be decomposed with formation of sulphur and gaseous carbon monosulphide. When the gas resulting from the discharge tube is passed through a tube cooled by liquid air, the monosulphide is condensed along with the unchanged disulphide. If the condensing tube is removed from the liquid air and its temp. allowed to rise, the monosulphide polymerizes with explosive violence to form the brown, solid substance, $(\text{CS})_n$. The explosive properties of the product from the ozone tube are not due to the presence of impurities in the carbon disulphide, and it is formed at temp. between -80° and 220° , but the yield is less at the higher temp. In presence of excess of carbon disulphide vap., the gaseous monosulphide appears to be fairly stable under certain conditions. Some of it is still present after passing the product from the ozonizer through a tube immersed in boiling sulphur, or even through a short length of red-hot tube. A beam of light reveals no solid particles in the gas. If the gas is cooled in one tube at -120° followed by another at -185° , it is separated

into two parts—a white crystalline solid which melts only when the temp. has risen to nearly 0° , collects in the first tube; the substance which gives rise to the brown solid does not condense at -120° , but is collected at -185° . The product from the ozonizer is completely destroyed by passing through 10 cms. of a red-hot tube loosely packed with asbestos; it is also absorbed, destroyed, or caused to polymerize by cocoanut charcoal, either at -78° , or at 250° , or at the ordinary temp. When passed over finely shredded rubber some of the carbon disulphide is removed from the gas. The ozonizer product is destroyed by finely-divided platinum, nickel, or silver; ferric oxide (not ignited), yellow mercuric oxide, silver oxide, and barium peroxide react with it, giving sulphides. Solid potassium hydroxide, silver nitrate, lead acetate, and sodium peroxide have little or no action. Nitric acid and conc. sulphuric acid bring about decomposition. Mixtures of carbon disulphide vapour with hydrogen, nitrogen, ether, methyl iodide, or chloroform have no effect on the phenomena observed. The vap. of thiocarbonyl chloride, ethyl thiocarbonate, ethyl dithiocarbonate, ethyl tri-thiocarbonate, and thiophene do not give rise to carbon monosulphide. The stability at high temp. is consistent with the behaviour of an endothermic substance. At the ordinary temp. the gaseous monosulphide polymerizes rapidly, even at low press. and in presence of a large excess of carbon disulphide. Comparisons of the brown carbon monosulphide produced in different ways show that they have probably different degrees of polymerization. The sp. ht. between 15° and -185° of the polymeric form of carbon monosulphide obtained from thiocarbonyl chloride is 0.127, the mol. ht. being 5.59, as compared with the calculated value 5.556. The heat of combustion is 178,050 cals., and the heat of formation 10,000 cals.

H. Kolbe² prepared **thiocarbonyl chloride**, CSCl_2 , the sulphur analogue of carbonyl chloride, COCl_2 , by the action of dry chlorine on carbon disulphide. From H. Müller's observations it follows that if iodine is dissolved in the carbon disulphide, the action is accelerated; with a boiling soln. sulphur chloride, carbon tetrachloride, and thiocarbonyl chloride are produced. H. Kolbe also made thiocarbonyl chloride by passing a mixture of hydrogen sulphide and the vap. of carbon tetrachloride through a red-hot tube: $\text{CCl}_4 + \text{H}_2\text{S} = 2\text{HCl} + \text{CSCl}_2$. G. Gustavson made it by heating carbon tetrachloride and sulphur in a sealed tube at 180° – 200° . R. de Fazzi said that the yield is small. B. Rathke observed that it is formed when thiocarbonyl tetrachloride, CSCl_4 , is reduced with powdered silver; or, according to P. Klason, when reduced with tin and hydrochloric acid. M. Kern and M. Sandoz warmed 30 parts of thiocarbonyl tetrachloride with 37 parts of dihydrated stannous chloride, 10 parts of conc. hydrochloric acid, and 7 parts of water in a closed vessel for 12 hrs. at 30° – 35° . J. W. James obtained it by the action of chlorine on methyl thiocyanate. P. F. Frankland and co-workers made it by reducing thiocarbonyl tetrachloride with tin and hydrochloric acid, using 550 grms. of thiocarbonyl tetrachloride, 175 grms. of tin, and 500 c.c. of a mixture of equal vols. of commercial hydrochloric acid and water. The thiocarbonyl tetrachloride is added as rapidly as is consistent with the efficient condensation of the distillate. The yield is 55–60 per cent. R. de Fazzi found that the action of iron on thiocarbonyl tetrachloride may give ferrous chloride and carbon tetrachloride, yet, with certain catalysts, the reaction may proceed: $\text{CCl}_3\text{SCl} + \text{Fe} \rightarrow \text{FeCl}_2 + \text{CSCl}_2$, with an 80 per cent. yield. He also found that sulphur does not react with carbon tetrachloride, even at the b.p., but in a sealed tube at 200° there is a slight reaction: $\text{CCl}_4 + 3\text{S} \rightarrow \text{CSCl}_2 + \text{S}_2\text{Cl}_2$, the yield is slightly increased if a little iodine be present; and if a mixture of a little iodine with sulphur and carbon tetrachloride be boiled for a long time a little thiocarbonyl chloride is formed. Powdered iron can replace iodine as catalyst; red phosphorus and phosphorus pentasulphide do not act as catalysts. Ferrous sulphide and carbon tetrachloride do not act below 100° , but if iodine be present, a little thiocarbonyl chloride is formed; and ferrous sulphide and carbon tetrachloride, without iodine, in a sealed tube gave a larger yield than any other substances tried: $\text{CCl}_4 + \text{FeS} = \text{FeCl}_2 + \text{CSCl}_2$.

Thiocarbonyl chloride, also called *thiophosgene*, is a red mobile liquid with a suffocating odour, and decomposes in moist air giving off fumes. O. S. Billeter and A. Strohl gave 15085 for the sp. gr. at 15°; and 72.8° for the b.p. at 730 mm. P. Klason gave 73.5° for the b.p. at 760 mm. P. Klason, and H. Bergreen said that it decomposes a little when heated to 200°, forming carbon disulphide and tetrachloride. G. Carrara found the index of refraction for the *D*-line to be 1.54424. B. Rathke said that the compound decomposes into *trichloromethyl-dithioformic chloride*, CCl_3CSSCl , when exposed to sunlight, but if thoroughly purified, no change was observed. According to B. Rathke and co-workers, O. S. Billeter and co-workers, and P. Klason, if exposed for some months to sunlight, polymerization occurs, and a colourless crystalline solid is formed; it has a slight smell, is unchanged in air; and melts at 112.5°. It absorbs water vapour, and at 180° is transformed into the liquid. H. Kolbe, and H. Bergreen observed that water slowly decomposes thiocarbonyl chloride in the cold, and more rapidly when heated, forming carbon dioxide, hydrogen chloride and sulphide. B. Rathke found that with an aq. soln. of potassium hydroxide it is immediately decomposed. P. Klason, and O. S. Billeter and A. Strohl said that when treated with alcohol, carbonyl sulphide, ethyl chloride, and *carbonyl hydrosulphotrisulphonate*, $\text{HS.C(HSO}_3)_3$, are formed. P. Klason found that when thiocarbonyl chloride is treated with chlorine, it forms thiocarbonyl tetrachloride; and when treated with sulphur in a sealed tube at 130°–150°, it forms chlorodithioformic chloride, Cl.CSSCl . According to B. Rathke, aq. ammonia quickly decomposes thiocarbonyl chloride, forming ammonium thiocyanate, etc. H. Bergreen found that when dried ammonia is passed into an ethereal soln. of thiocarbonyl chloride, ammonium chloride, and thiocyanate are formed, and when treated with ammonium chloride at 200°, or, according to B. Rathke, with aluminium chloride, carbon disulphide and tetrachloride are formed. Reactions with organic compounds have been studied by B. Rathke, H. Bergreen, P. Klason, G. M. Dyson and H. J. George, and O. S. Billeter and co-workers.

According to B. Rathke,³ when chlorine is passed into a soln. of one part of iodine in 500 parts of carbon disulphide, sulphur chloride and thiocarbonyl tetrachloride, CSCl_4 , are formed. The products of the reaction can be separated by fractional distillation under reduced press. This compound can be regarded as *trichloromethylsulphur chloride*, CCl_3SCl , or *perchloro-methylmercaptan*. P. Klason made it by the action of chlorine on thiocarbonyl chloride in the cold; and J. W. James, by the action of chlorine on methyl thiocyanate. P. F. Frankland and fellow-workers made it by the action of chlorine on carbon disulphide in the presence of iodine:

Add 4 grms. of iodine to 2 kgrms. of carbon disulphide dried over calcium chloride; pass chlorine from a cylinder and dried by calcium chloride, so that the temp. does not rise above 20°–25°, and almost all the gas is absorbed. When the increase in weight is approximately that required by $2\text{CS}_2 + 5\text{Cl}_2 = 2\text{SCl}_2 + \text{S}_2\text{Cl}_2$, the passage of chlorine is stopped, and the mixture is run in a thin stream into hot water contained in a large vessel through which a current of steam is blown so as to decompose the sulphur chloride, and to distil off the tetrachloride. Much sulphur dioxide is evolved, and a train of four condensers is used to collect the required product. The first condenser is air-cooled; the second is cooled by ice; and the last two are cooled by a mixture of ice and salt. The tetrachloride is again distilled in steam; dried over calcium chloride; and distilled with a fractionating column until the temp. rises to 140°.

Thiocarbonyl tetrachloride is a golden-yellow liquid, with an intense disagreeable odour, and it strongly attacks the eyes and respiratory organs. B. Rathke found the sp. gr. to be 1.712 at 12.8°/0°; G. Carrara gave 1.71785 at 11°/4°; and P. Klason, 1.712 at 0°, 1.7049 at 11°, and 1.6953 at 17.5°. B. Rathke gave 146° to 148° for the b.p.; and P. Klason, 149°. The boiling liquid suffers a slight decomposition. When heated in a sealed tube at 200°, B. Rathke found that carbon tetrachloride and sulphur chloride are formed. G. Carrara found 1.54835 for the index of refraction with the *D*-line. According to B. Rathke, when heated with water at 160°, carbon dioxide, hydrogen chloride, and sulphur are formed; the

decomposition is rapid in soln. of potassium hydroxide. P. Klason, and J. W. James found that chlorine alone, or better in the presence of a trace of iodine, transforms **1** into carbon tetrachloride and sulphur chloride. P. Klason found that with sulphur at 150°–160°, carbon tetrachloride, thiocarbonyl chloride, hexachlorodimethyl di- and tri-sulphide are formed. Aq. ammonia was found by B. Rathke to give ammonium thiocyanate; and cold nitric acid, sp. gr. 1.2, forms *trichloromethyl-sulphuryl chloride*, $\text{CCl}_3\text{SO}_2\text{Cl}$. P. Klason found that tin and hydrochloric acid reduce the tetrachloride to thiocarbonyl chloride, and with silver dust, hexachlorodimethyl disulphide is formed. M. Albrecht obtained carbon hydrosulphopotassium trisulphonate, $\text{HS.C(KSO}_3)_3$, by the action of potassium sulphite. B. Rathke investigated a number of reactions with organic compounds.

P. Klason⁴ made **thiocarbonyl thiochloride**, CS_2Cl_2 , by heating a mixture of sulphur and thiocarbonyl chloride in a sealed tube between 130° and 150°, and fractionally distilling the product in vacuo. It is a yellow oil, which boils in vacuo at about 140°; it is decomposed by chlorine into thiocarbonyl tetrachloride, and by sulphur at 160° into sulphur chloride and carbon disulphide. P. Klason, and B. Rathke made **hexachlorodimethyl disulphide**, $\text{CCl}_3\text{S.S.CCl}_3$, by the action of powdered silver on an excess of thiocarbonyl tetrachloride. According to P. Klason, the viscid yellow oil boils undecomposed in vacuo at 135°; and is but slightly volatilized in steam. It decomposes when heated under ordinary press., forming thiocarbonyl chloride and tetrachloride. When heated with sulphur at 170° it forms **hexachlorodimethyl trisulphide**, $\text{CCl}_3\text{S.S.S.CCl}_3$. The same compound is produced when thiocarbonyl tetrachloride is heated above its b.p., or treated with sulphur at 150°–160°. B. Rathke made it by allowing a mixture of thiocarbonyl chloride and sulphur chloride to stand for a long time; and it is present in the products of the action of dried chlorine on iodiferous carbon disulphide. This compound can be crystallized from alcohol when it furnishes colourless prisms, which are easily soluble in ether, carbon disulphide, and warm alcohol. It fuses at 57.4°, and it distils undecomposed in vacuo at 190°; but under ordinary press. it furnishes thiocarbonyl chloride, carbon tetrachloride, sulphur chloride, and thiocarbonyl tetrachloride as decomposition products. The corresponding compound, **hexabromodimethyl trisulphide**, $\text{CBr}_3\text{S.S.S.CBr}_3$, was made by C. Hell and F. Urech by the action of bromine on carbon disulphide; by A. von Bartsch by the action of sulphur on carbon tetrabromide; and by W. Plotnikoff by treating CS_2Br_4 AlBr_3 , successively with water, alcohol, and ether, and crystallizing from petroleum-ether, when clear prisms were obtained. If crystallized from ether the crystals are tabular. A. von Bartsch gave 123°–124° for the m.p., and C. Hell and F. Urech, 125°, and they added that the compound becomes red on melting. It is insoluble in water; sparingly soluble in cold ether, alcohol, and glacial acetic acid; soluble in benzene, petroleum ether, and chloroform; and very soluble in carbon disulphide and bromine. It decomposes slowly when boiled with alcohol; at ordinary temp., 100 parts of boiling alcohol, said C. Hell and F. Urech, dissolve 5.5 parts of the compound; 100 parts of ether dissolve 2.35 parts at 0°, and 4.95 parts at the b.p. They also found it to dissolve without decomposition in boiling conc. sulphuric acid. When heated with an excess of bromine and water, in a sealed tube, carbon dioxide, carbonyl sulphide, hydrogen bromide, and sulphuric acid are formed. Dñ. aq. soln. of the alkali hydroxides have no action in the cold; but if heated with conc. soda-lye or baryta-water, when air is excluded, polysulphide, carbonate, and bromide are formed but no sulphate is produced; but if boiled with an excess of lead oxide and water, a sulphate is formed. According to A. von Bayer, hexabromodimethyl trisulphide forms addition products with methyl iodide and with iodoform.

* According to C. Hell and F. Urech, when hexabromodimethyl trisulphide is heated above its m.p., small quantities of a compound of unknown constitution: $\text{C}_6\text{Br}_4\text{S}_8$, are produced, and A. von Bartsch obtained the same compound by the action of carbon tetrabromide on sulphur. C. Hell and F. Urech said the indigo-blue powder retains 2 to 3 mols. of water, and if heated for a long time at 150°, A. von Bartsch found the water was expelled. The

blue colour is attributed to the presence of the $-S.S-$ group. The anhydrous compound is scarcely volatile. A. von Bartsch and C. Hell and F. Urech said that the compound is insoluble in ordinary solvents, easily soluble in phenol, and in hot conc. sulphuric acid forming a blue soln.; it is sparingly soluble in hot aniline; and easily soluble in conc. nitric or hydrochloric acid, forming a violet soln. which later becomes red.

§ 40. The History, Occurrence, and Preparation of Carbon Disulphide

In 1796, W. A. Lampadius¹ attempted to determine the amount of sulphur in a sample of iron pyrites; he heated a mixture of that mineral with carbon, and obtained an oily, sulphurous, volatile liquid. He tried heating the mineral with wood, anthracite, etc., and still obtained the oily liquid accompanied by hydrogen sulphide, volatile hydrocarbons, and empyreumatic matters. He called the product *le soufre liquide*, and *le alcool de soufre*, and regarded it as a compound of sulphur and hydrogen. In 1802, F. Clément and J. B. Désormes tried to find if charcoal which had been calcined still contained hydrogen, and, on heating the charcoal with sulphur, obtained a liquid which they regarded as *le bisulfure d'hydrogène*. They found that it did not behave towards a soln. of lead acetate like hydrogen sulphide, and finally concluded that it contained no hydrogen, and they named it *le soufre carburé*. They tried without success to find the exact proportions of sulphur and carbon in *le soufre carburé*. Some unsatisfactory observations were made by A. B. Berthollet, J. B. Trommsdorff, H. Davy, L. N. Vauquelin and P. J. Robiquet, and M. Cluzel, from which it was not made clear whether or not the liquid contained hydrogen, and even nitrogen. In a report by A. B. Berthollet, some experiments by L. N. Vauquelin are described in which the vapour was passed over heated

copper, whereupon carbon and copper sulphides were formed, and it was concluded that the former contained 14-15 parts of carbon and 85-86 parts of sulphur. The compound was also analyzed by J. J. Berzelius and A. Marcet. These analyses show that the liquid is carbon disulphide, CS_2 . J. J. Berzelius made a special study of the properties of the compound in 1823; and W. C. Zeise investigated its action on a number of oxides, alcohol, etc. J. P. Wibaut showed that sulphur is retained by carbon which has been heated in the vap. of sulphur, and he assumes that the product is a mixture of carbon and a sulphide of carbon which is non-volatile at 1000° .

Carbon disulphide has been found in the petroleum and benzenes of commerce by H. Hager,² C. Vincent and B. Delachanal, and K. Helbing; in the gases from cess-pools, by M. Scanlan and A. Anderson; in coal gas, by A. W. Hofmann, and R. Witzcek; and in oil of mustard (allyl thiocyanate), by A. W. Hofmann, and E. Mylius.

F. Clément and J. B. Désormes,³ G. J. Mulder, etc., prepared carbon disulphide by heating carbon in the vap. of sulphur. The volatile compound of carbon and sulphur is condensed in vessels surrounded with cold water. The product is contaminated with free sulphur, which volatilizes with the carbon disulphide; some hydrogen sulphide is formed at the same time by the action of sulphur on the hydrogen in the charcoal. T. Sidot showed that at a mean red heat a greater yield is obtained than at a dull red or a bright red-heat. M. Berthelot, and W. Stein showed that the reaction is reversible, for, when carbon disulphide is heated to redness, it decomposes into its elements: $\text{CS}_2 = \text{C} + \text{S}_2$. Accordingly, F. Koref found that the equilibrium constant $K = [\text{S}_2]/[\text{CS}_2]$ is 0.078 at 823° ; 0.115 at 9.6° ; 0.179 at 1009° ; and 0.258 at 1383° . He found the observed results at $T^\circ \text{K.}$ can be represented by $\log K = -2740/T + 1.38$. In the decomposition experiments, the value of the constant fell with time owing to the formation of silicon sulphide, SiS_2 , which acts as a carrier of sulphur, re-converting the carbon set free into carbon disulphide. In the manufacturing process, the charcoal is contained in vertical cast iron or earthenware retorts, 10-12 ft. high and 1-2 ft. diam., set in a suitable furnace. The heat of the furnace melts the sulphur placed in a hopper near the base of the retort, the sulphur vapour rises through the red-hot charcoal and forms carbon disulphide which escapes at the top; the end of the exit pipe dips under water where much of the carbon disulphide is condensed. The condensation is completed in long condensing coils—30 ft. long—and the escaping hydrogen sulphide can be absorbed by slaked lime (E. Diess), or ferric hydrate (A. Payen). Various modifications have been suggested by J. Farbaky, P. Schubert, E. Diess, A. Galy-Cazalat and A. Huillard, I. Singer, Chemische Fabrik Griesheim-Electron, etc. A. E. Delph found that the deposit which forms on iron or steel in contact with carbon disulphide vap. at 400° , can be prevented by a thin coating of aluminium. In E. R. Taylor's electric process a cylindrical furnace 40 ft. high and 16 ft. in diameter is packed with coke from the top, Fig. 59; the coke is renewed through the side hopper C. An alternating current is sent through the electrodes E set at right angles to one another at the base of

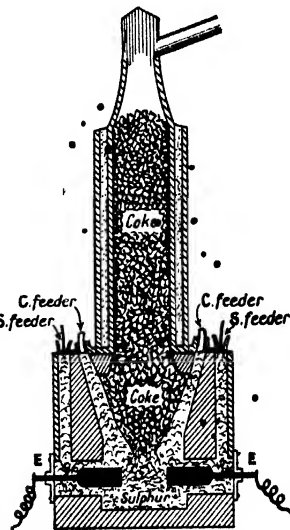

FIG. 59.—Taylor's Carbon Disulphide Furnace.

the furnace. The heat melts the sulphur on the floor of the furnace; the vap. of sulphur rises through the coke, forming carbon disulphide. Fresh sulphur is introduced through the hopper shown in the diagram. The carbon disulphide passes off at the top of the furnace, and is condensed in the condensing coils. The electrical process is practically continuous and is free from the troublesome leakages and heat-losses incidental to the retort process. The subject has been discussed by G. A. Richter, and B. Waeser.

B. Rasseow and K. Hoffmann have investigated the conditions under which carbon disulphide is formed from sulphur dioxide and heated wood charcoal. At 700°, only traces of carbon disulphide are formed. Above 750°, the yield gradually increases, carbon oxysulphide, carbon dioxide, sulphur vap. and small quantities of carbon monoxide also being formed. At 850°–900°, the yield of carbon disulphide reaches a maximum and accounts for 35 per cent. of the sulphur dioxide, 55 per cent. being found as oxysulphide and 10 per cent. as free sulphur. At temp. above 900°, the free sulphur increases at the expense of the carbon disulphide and oxysulphide, and above 1100° the sole products of the reaction are free sulphur and carbon monoxide. The low yield obtainable and the danger, and the trouble attending the handling of the oxysulphide, render this method of preparing carbon disulphide impracticable for industrial purposes. W. A. Lampadius, and E. and L. Labois obtained carbon disulphide by heating a mixture of carbon with iron or copper pyrites, or antimony sulphide. M. Berthelot, C. Brunner, W. Stein, G. J. Mulder, A. Schrötter, T. Sidot, P. A. Favre and J. T. Silbermann obtained it by heating various carbonaceous substances—horn, wax, sugar, etc.—with sulphur; and A. Mitschsch and E. Willroth, by heating a mixture of carbon monoxide and sulphur vap. along with a suitable catalyst. B. Rathke found that it is formed by heating carbon tetrachloride and phosphorous sulphide in a sealed tube at 200°; J. Gadamer, by heating allyl thiocyanate with water in a sealed tube at 100°–105°; A. W. Hofmann, by distilling natural oil of mustard; F. A. Went, by distilling cultivations of *schizophyllum lobatum* a fungus which occurs in Java on old fallen branches of *pectocarpus bamboo* stems, etc.—if in hydrogen, the fungus produces no carbon disulphide, or only traces; G. Capelle, by passing acetylene into molten sulphur; and R. Willstätter and T. Wirth, by heating thioformamide hydrochloride out of contact with air.

The purification of carbon disulphide.—When the carbon disulphide is required of a high degree of purity, B. Delachanal and A. Mermet⁴ recommended preparing it by the decomposition of a metal thiocarbonate. The crude carbon disulphide obtained by the action of sulphur vap. on carbon has a fetid odour due to the presence of organic sulphur compounds, hydrogen sulphide, etc. The crude liquid also has sulphur in soln., and this can be largely removed by distillation. E. Deiss, for instance, fractionally distilled the crude liquid and found that the constituents with a repulsive odour collected in the first fractions, and sulphur in the last fractions. The middle fractions were purest. M. Bonière purified the crude liquid by distillation from a conc. soln. of sodium hydroxide, and passing the vapours through alkaline liquids and soln. of salts of iron, lead, or copper. S. Cloëz purified carbon disulphide by agitation with finely powdered mercuric chloride, followed by distillation over an inodorous fat. N. A. E. Millon, and A. Commaïlle distilled the liquid from milk of lime, and allowed it to stand in contact with litharge or with copper, zinc, or iron turnings; G. C. Wittstein expressed doubts as to the efficacy of this procedure. I. Singer washed the liquid with milk of lime and distilled the product mixed with a soln. of lead acetate. T. Sidot, and S. Cloëz agitated the impure liquid with mercury; and S. Kern, with a mixture of lead and lead nitrate. L. H. Friedburg distilled the liquid over palm oil, digested the product with fuming nitric acid, washed with water, and rectified. P. C. Marquart stated that the violet colour observed when carbon disulphide is treated with fuming nitric acid is due to iodine nearly always present as an impurity in the acid. E. Allary treated the crude liquor with potassium perman-

ganate; and E. Obach distilled the liquid over quicklime; agitated the product with potassium permanganate, mercury, and mercuric sulphate, and finally rectified it. P. Palmieri agitated 100 parts of the crude liquid with 2-3 parts of dried copper sulphate; and subsequently rectified over dry copper sulphate. The result was good. A. Chenevier treated a litre of crude carbon disulphide with 0.5 c.c. of bromine for 3-4 hrs., removed the excess of bromine by potash-lye, or copper turnings, and distilled the product. M. von Unruh agitated the crude liquid with mercury, and porous calcium chloride, and distilled it in the dark. O. Ruff and H. Golla digested the carbon disulphide with a sat. soln. of sodium sulphide for 24 hrs. The sodium thiocarbonate was separated, treated with copper sulphate, and the resulting copper thiocarbonate decomposed by passing steam into the soln. The pure carbon disulphide so obtained was distilled in steam, and finally dried with phosphorus pentoxide.

§ 41. The Physical Properties of Carbon Disulphide

Impure carbon disulphide is a liquid which has *l'odeur des œufs pourris*, but the smell of the purified liquid is not unpleasant, and it recalls that of chloroform. W. A. Wahl¹ obtained spherulitic crystals by cooling the liquid, and, when these were melted and recrystallized, long needle-like crystals, very strongly doubly refracting, were formed which belonged to the monoclinic or triclinic system—probably the latter. V. and C. Meyer found the vapour density to be 2.68 when the theoretical value for CS_2 is 2.62. A. Schulze found that the vap. density of carbon disulphide indicates a 2 per cent. association. The vap. density (air unity) and specific volume (c.c. per gram) of the vap. of carbon disulphide between 48.38° and 85.03° were determined by A. Wüllner and O. Grottrian; and between -29.34° and the critical temp. by A. Battelli. R. Lorenz and W. Herz, and G. M. Schwab measured the mol. vol. A. Battelli gave.

	-29.34°	-8.26°	78.82°	130.48°	171.52°	209.32°	273.0°
Sp. vol.	20482.3	1251.3	137.21	46.162	23.892	10.094	2.718
Vap. density	2.6205	2.6539	2.76205	2.9206	3.1218	3.8057	7.8280

A. O. Rankine estimates the collision area of the mol. of carbon disulphide vap. to be between 1.37×10^{-5} and 1.23×10^{-15} sq. cm. J. L. Gay Lussac gave 1.293 for the specific gravity of the liquid at 0° , and 1.271 at 15° ; H. L. Buff gave 1.29858 at 0° , 1.27901 at 10° , 1.26652 at 17° , and 1.227431 at 46° . J. H. Gladstone gave 1.2909 at 23° , and 1.2591 at 30° ; R. Nasini, 1.2634 at $20/4^\circ$; C. E. Linebarger, 1.25958 at 25° ; A. Haagen, 1.2661 at 20° ; R. Schiff, 1.2233 at $46.5/4^\circ$; T. E. Thorpe, 1.29215 at $0/4^\circ$, and 1.22242 at $46.04/4^\circ$; H. V. Regnault, 1.2823 at 5° – 10° , 1.275 at 10° – 15° , and 1.2676 at 15° – 20° ; J. I. Pierre, 1.29312 at 0° ; A. Winkelmann, 1.2665 at 16.06° ; J. Timmermans, 1.29270 at 0° – 4° ; W. Ramsay, 1.2176 at 43° ; L. H. Friedburg, 1.266 at 15.2° ; and J. Drecker, 1.26569 at 17.86° , 1.26446 at 18.58° , 1.25031 at 28.21° , and 1.23863 at 35.96° . E. Beckmann found the sp. gr. at the b. p. to be 1.2223, and M. von Unruh, 1.2209. Values were also obtained by W. A. Lampadius, F. Clément and J. B. Désormes, M. L. Frankenheim, A. de la Rive, H. F. Weber, F. D. Brown, J. J. Berzelius and A. Marcet, M. Cluzel, J. P. Couerbe, A. Ritzel, J. W. Brühl, etc. A. Wüllner represented the sp. gr., S , at 0° between 7° and 21° by the equation $S = 1.29366 - 0.001506\theta$; J. I. Pierre gave $1.292 = S(1 + 0.001140\theta + 0.00137\theta^2 + 0.001912\theta^3)$; and J. Timmermans for the sp. gr. at T° K., upwards from absolute zero, $S = 1.67367 - 0.00130856T - 0.003180T^2$. The sp. gr. of binary mixtures of carbon disulphide with ethyl and propyl alcohols were determined by J. Holmes, with acetic ether, toluene, and chloroform, by C. E. Linebarger; and with carbon tetrachloride, and benzene, by F. D. Brown. The changes which occur on mixing carbon disulphide with alcohol, chloroform, or benzene were measured by F. Guthrie. O. Drucker found that the molecular elevation of the critical solution temperature for carbon disulphide and methyl alcohol is specific for each substance added to the binary system. N. Schoorl and A. Regenbogen studied the ternary system—water, alcohol, and carbon disulphide.

The coeff. of compressibility, β , of carbon disulphide was found by M. Amaury and C. Descamps² at 14° to be 63.5×10^{-6} per atm.; L. P. Cailletet, 98×10^{-6} per atm. at 8° and 607 atm.; W. C. Röntgen, 89×10^{-6} at 18° ; E. H. Amagat, 87×10^{-6} per atm. between 9 and 38 atm. at 15.6° , and 174×10^{-6} at 99.3° ; or, 0.090 at 20° , 0.03107 at 40° , 0.03128 at 60° , and 0.03149 at 80° ; and P. W. Bridgman gave 0.032 at 20° , 0.03107 at 40° , 0.03133 at 60° , and 0.03150 at 80° . The last-named also found the effects of press. (kgms. per sq. cm.) and temp. on the vol. of carbon disulphide indicated in Table XXVII. W. Seitz made observations on this subject. According to A. Ritzel, at a press. p atm., the compressibility coeff. is:

$20^\circ \beta$	107	262.5	441.5	679.5
$\beta \times 10^4$	77.2	66.6	60.1	51.0
$25^\circ \beta$	115.5	236.0	342.0	495.5
$\beta \times 10^4$	83.2	71.9	69.3	61.7

A. Schulze found the p -curves of carbon disulphide at 78.82° , and 130.48° show that the mol. association decreases with increasing temp.; and at constant temp., increases with increasing press. Compressibility measurements show at 80° , 0.5 per cent. more association at 2 atm. than at 1 atm. press.

TABLE XXVII.—THE EFFECTS OF PRESSURE AND TEMPERATURE ON THE VOLUME OF CARBON DISULPHIDE.

Press.	20°	30°	40°	50°	60°	70°	80°
1°	1.0235	1.0357	1.0490	1.0630	1.0775	1.0928	1.0992

A. Ritzel measured the compressibility of mixtures of carbon disulphide and acetone. T. M. Gardner studied the adiabatic expansion of carbon disulphide vap.; and A. Horstmann, H. Herwig, T. E. Thorpe, and E. H. Amagat, the expansion and compression of the vap. R. Gans discussed the symmetry of the mol. of carbon disulphide. W. Ramsay and J. Shields found the surface tension of the liquid in contact with the sat. vap. to be $\sigma=33.58$ dynes per cm. at 19.4° and at 46.1° , $\sigma=29.41$ dynes per cm.; the specific cohesion $a^2=5.40$ sq. mm. at 19.4° , and 4.90 sq. mm. at 46.1° . S. von Wroblewsky examined the effect of dissolved carbon dioxide on the surface tension of the disulphide. The mean molecular surface energy was 2.022, the characteristic of a non-associated liquid. M. L. Krankenheim gave for σ dynes per cm., and a^2 sq. mm., 32.2 and 5.10 at 0° , and 29.8 and 4.48 at 25° ; W. F. Magie gave 31.74 and 5.071 at 20° ; and A. M. Worthington, 29.33 and 4.71 at 25° . A. Ritzel gave $\sigma=31.64$ dynes per cm. at 25° . R. Lorenz and W. Herz gave $\sigma=27.3$ at the b.p., and 48.9 at the m.p. The surface tensions of mixtures of carbon disulphide and chloroform were determined by W. Ramsay and E. Aston. A. Wikander gave for the viscosity of the liquid (water unity) at 20° , 0.205; at 25° , 0.191; and at 30° , 0.190. T. E. Thorpe and J. W. Rodger gave for the viscosity coeff., η :

η	0.40°	0.45°	19.34°	30.30°	40.62°	45.96°
	0.00428	0.00397	0.00367	0.00342	0.00317	0.00306

and they represented the viscosity coeff. at θ° by $\eta=24.379(199.17+\theta)^{-1.6328}$. Observations were also made by M. Brillouin. The viscosity of the vap. at 0° was found by J. Puluji to be 0.0000924. V. Henri discussed the electronic structure of the mol. The viscosity of binary mixtures of carbon disulphide with ethyl alcohol was determined by A. E. Dunstan; with ether, acetic ether, benzene, and toluene, by C. E. Linebarger. P. Walden gave 2170 atm. for the internal pressure of carbon disulphide; and I. Traube gave 1980 atm. F. S. Mortimer calculated the internal press. from solubility data. D. L. Hammick used for the constant a in J. D. van der Waals' equation, 0.02412 atm. J. E. Mills studied the molecular attraction. J. Stefan found the diffusion coeff. of air in carbon disulphide to be 0.00995. J. Duclaux and J. Errera studied the filtration of carbon disulphide through colloidal membranes. A. Masson found the velocity of sound in carbon disulphide at 0° to be 189.00 metres per sec.; A. Lechner, 204.7 metres per sec. at 48° ; and E. H. Stevens, in the vap. at 99.7° , 223.2 metres per sec.

The coeff. of thermal expansion of carbon disulphide has been determined by G. W. Muncke, who gave for the vol., v , at θ° , $v=v_0(1+0.001125691\theta$

$+0.0_5171504\theta^2 + 0.0_5127166\theta^3$), where v_0 is the vol. at 0° ; J. I. Pierre gave $v = v_0(1 + 0.0011398\theta + 0.0_513707\theta^2 + 0.0_519123\theta^3)$; G. A. Hirn $v = v_0(1 + 0.00116806\theta + 0.0_516490\theta^2 - 0.0_581112\theta^3 + 0.0_56005\theta^4)$, between 30° and 160° ; and T. E. Thorpe $v = v_0(1 + 0.00115056\theta + 0.0_5111621\theta^2 + 0.0_517475\theta^3)$. P. Walden gave $v = v_0(1 + 0.00117\theta)$ between 0° and 30° . E. H. Amagat found that under normal press., ether is more expansible than carbon disulphide, under 2500 atm. press., the expansibility of the two liquids is the same; and under 3000 atm., the expansibility of carbon disulphide is the greater. W. Seitz made observations on the thermal expansion of carbon disulphide at low temp.; and J. J. Saslawsky studied the relation between the thermal expansion and the critical temp. The thermal conductivity of carbon disulphide was found by R. Goldschmidt to be 0.0003879 cal. per cm. per sec. per degree at 0° ; by H. F. Weber, 0.000417 at 5.4° ; and 0.000343 between 9° and 15° ; by L. Graetz, 0.000267 at 13° ; by C. Chree, 0.000537 at 15.5° ; and by A. Winkelmann, 0.00200 at 10° to 18° . E. Pauli found the ratio of the thermal conductivity of the vapour at 100° and at 10° to be $k_{100}/k_0 = 1.516$. P. W. Bridgman gave 0.000382 at 30° and 0.000362 at 75° ; and if the value at 0 kgrm. per sq. cm. press. be unity at 30° , the value at 1000 kgrms. per sq. cm. is 1.174, and at 12,000 kgrms. per sq. cm., 1.962.

The specific heat of carbon disulphide was found by A. Battelli ⁴ to be 0.195 at -96° ; and 0.238 at 0° ; H. V. Regnault gave 0.2303 at -30° , 0.2352 at 0° ; and 0.2401 at 30° , and he represented the sp. ht. at θ° by $0.2352 + 0.000162\theta$; G. A. Hirn gave 0.2388 for the sp. ht. at 30° ; W. Sutherland, 0.260 at 120° and 0.2882 at 160° ; and C. Forch gave 0.242 at 18° . H. V. Regnault found 0.160 for the sp. ht. of carbon disulphide vap. at constant press. between 86° and 190° ; and M. Pier gave 0.137 for the sp. ht. at constant vol. between 0° and 2000° . K. Zakrzewsky found for the sp. ht. at constant vol. to be:

Sp. ht.	-90°	-70°	-50°	-20°	0°
	0.110	0.114	0.121	0.139	0.160

For the ratio of the two sp. hts., P. A. Müller gave 1.189 between 21° and 40° ; K. Bindel, 1.205 between 3° and 67° ; E. H. Stevens, 1.234 at 99.7° ; and R. Thibaut, 1.199 at 17° and 202 mm. The sp. hts. of binary mixtures of carbon disulphide and ethyl alcohol, chloroform, and benzene have been determined by J. H. Schüller. A table of the vapour pressures of carbon disulphide between -30° and the critical temp., at intervals of 10° , has been determined by A. Battelli. He found at -30° , 7.97 mm.; at -20° , 42.41 mm., and at -10° , 128.39 mm. At the critical temp. 273.05° , the critical press. was 55,380 mm. The other results are indicated in Table XXVIII. H. V. Regnault represented his observations at θ° between -20°

TABLE XXVIII.—VAPOUR PRESSURE OF CARBON DISULPHIDE
(mm. mercury).

Temp	0°	10°	20°	30°	40°	50°	60°	70°	80°	90°
1	128.39	198.01	296.48	432.76	616.75	859.49	1172.9	1560.6	2062.1	2662.8
2	3383.4	4234.4	5225.0	6362.0	7651.6	9094.9	10963.2	12448.8	17095.1	20317.8
3	33813.3	27555.4	31518.9	36675.0	39993.7	44444.6	48997.2	53622.0	—	—

and 150° , by $\log p = a + b\theta + c\theta^2$, where $a \log p = 5.401162 - 3.4405663a\theta + 20 - 0.28573686\theta^2$, where $\log a = 1.9977628$, and $\log \beta = 1.9911997$. C. Antoine represented his results by $\log p = 1.2020(5.8181 - 1000(\theta + 246)^{-1})$. A. Jarolimek gave $\theta = 120p^{0.25} - 73.5$. W. Sajontschewsky and M. Avenarius measured the vap. press. between 140° and 271.8° ; and A. Wüllner and O. Grotian between 20.44° and 85.01° . A. Juliusberger studied the subject. A. Stock and co-workers represented their measurements on the vap. press. of carbon disulphide between 11° and -181° by $\log p = -1682.38T^{-1} + 1.75 \log T - 0.0052980T + 5.44895$. C. E. Carbonelli, and R. Lorenz made a study of the variation of the vap. press.

of carbon disulphide with temp.* F. Guthrie studied the vap. press. of binary mixtures of carbon disulphide with ether or chloroform; J. von Zawidzky, of carbon disulphide with methylal, or acetone; and W. K. Lewis and E. V. Murphree, of carbon disulphide and water. M. A. Rosanoff and C. W. Easley studied the distillation of binary mixtures of carbon disulphide with carbon tetrachloride, or benzene; and C. Drucker, and E. C. McKelvy and D. H. Simpson, mixtures of carbon disulphide with ethyl or methyl alcohol.*

S. von Wroblewsky, and K. Olzschewsky⁵ found that at about -116° , carbon disulphide freezes to a crystalline solid with a melting point of -110° . G. Caprara and A. Coppadoro gave -108.6° for the m.p.; J. Timmermans, -111.6° ; F. G. Keyes and co-workers, -112.97° ; L. Holborn and W. Wien, -112.8° ; and G. Tammann, -112.8° . The last-named also represented the effect on the m.p. of press. p kgrms. per sq. cm., $dT=0.0160p$. Observations on the boiling point of carbon disulphide were made by W. A. Lampadius, J. I. Pierre, J. L. Gay-Lussac, H. Kopp, A. Haagen, W. Ramsay, L. H. Kriedburg, J. M. Crafts, F. A. Henglein, W. Sajontschewsky, and M. Avenarius. For the b.p. R. Schiff gave 47.0° at 768.5 mm.; T. Andrews, 46.2° at 769 mm.; M. von Unruh, 46.25° at 760 mm.; T. E. Thorpe, 46.04° at 760 mm.; H. V. Regnault, 46.20° at 760 mm.; H. Arctowsky, 46.27° at 757 mm.; R. Nasini, 47.5° at 764 mm.; and J. Timmermans, 46.25° at 760 mm. H. B. Baker found the b.p. is raised a number of degrees if the carbon disulphide be very thoroughly dried. E. Hendrick discussed H. B. Baker's observations and enquiries if the presence of a trace of water separates or loosens molecular aggregates. According to M. von Unruh, the b.p. changes between 740° and 765 mm., 0.4144° for 10 mm. change of press.; this is eq. to 1° for 24.13 mm. change of press. He also found the molecular raising of the boiling point to be 2370 per 100 grms., or 1940 per 100 c.c. E. Beckmann gave for the b.p. constant 23.7 per grm. H. V. Regnault gave for the latent heat of vaporization, 90 cal. per grm. at 0° ; 100.48 cal. at 100° , and 102.36 cal. at 140° ; A. Winkelmann, 89.5 cal. at 0° ; F. Koref, 86.9 cal. at 14.1° ; K. Wirtz, 83.1 cal. at 46.1° ; D. L. Hammick, 85 cal. per gram; T. Andrews, 86.87 cal. at 46.2° ; and C. C. Person, 105.7 cal. at 46.6° . H. V. Regnault gave for the heat of vaporization at 0° , $90.00-0.08922\theta-0.0004938\theta^2$; and A. Winkelmann, $89.50-0.06530\theta-0.0010976\theta^2-0.0000034245\theta^3$. The rapid evaporation of carbon disulphide produces a low temp., and experiments on this subject were made by J. Murray in 1812.

M. Avenarius gave 276.0° for the critical temperature of carbon disulphide, and B. Galitzine, 279.6° . C. Cagniard de la Tour gave 275.0° for the critical temp., 77.8 atm. for the critical pressure, and 0.0096 for the critical volume. For the critical temp. and press., respectively, W. Sajontschewsky gave 271.46° and 74.7 atm.; J. B. Hannay and J. Hogarth, 272.96° and 77.9 atm.; J. Dewar, 277.7° and 78.1 atm.; J. B. Hannay, 277.68° and 78.14 atm.; and A. Battelli, 273.05° and 72.868 atm., and for the critical vol., 0.009011. The data of C. Cagniard de la Tour gave for J. D. van der Waals' constants $a=0.02185$, and $b=0.003225$; W. Sajontschewsky, $a=0.02166$, and $b=0.003339$; J. B. Hannay and J. Hogarth, $a=0.02166$, and $b=0.003209$; J. B. Hannay, $a=0.02197$, and $b=0.003227$; and A. Battelli, $a=0.02316$, and $b=0.003134$. W. Herz gave 3.17 for the chemical constant, and W. Nernst, 3.1.

Carbon disulphide is an endothermal compound. J. Thomsen⁶ gave for the heat of formation from amorphous carbon and rhombic sulphur, (C, 2S) $=CS_{2(gas)}-26.01$ Cals.; or $CS_{2(liquid)}-19.61$ Cals.; and from the diamond M. Berthelot and C. Matignon gave for the gaseous carbon disulphide -25.4 Cals., and for the liquid -19 Cals. M. Berthelot gave for the heat of combustion, $252.8-253.3$ Cals.; and J. Thomsen, 265.1 Cals. J. J. Berzelius and A. Marcat said that the temp. of combustion of carbon disulphide in oxygen is sufficient to melt platinum wire. The thermal values of binary mixtures of carbon disulphide with ethyl alcohol, and with benzene were determined by A. Winkelmann. A. Marcat discussed the production of cold by the evaporation of carbon disulphide.

Carbon disulphide has a high **refractive index** and a high **dispersion**. In this it is exceeded by very few liquids; those of methylene iodide, bromonaphthalene, and phenyl-mustard oil are greater. Hence, the use of carbon disulphide for filling hollow glass prisms for spectroscopic work. A large number of measurements of the refractive index has been made by E. E. Hall and A. R. Payne, etc.⁷ E. Flatoff's results, Table XXIX, show the effect of variations of temp. and of wave length, λ , on the refractive index. H. Rubens found for the ultra-red, at 20°:

λ	580	777	873	999	1164	1396	1745	1998 μ
μ	1.6275	1.6072	1.6017	1.5968	1.5928	1.5894	1.5856	1.5840

while F. F. Martens gave for the ultra-violet 2.159 when $\lambda=260\mu$, and W. Fricke gave:

λ	266	274	288	298	304	317	326	335 μ
μ	2.423	2.009	1.912	1.875	1.852	1.807	1.782	1.79

TABLE XXIX.—THE EFFECT OF TEMPERATURE AND WAVE-LENGTH OF LIGHT ON THE REFRACTIVE INDEX OF CARBON DISULPHIDE.

λ	-10°	0°	20°	40°
367.61	—	2.12321	2.08823	—
274.87	2.01983	2.03484	2.00474	1.97489
361.19	1.76695	1.75719	1.73806	1.71811
394.41	1.72888	1.71980	1.70180	1.68278
441.59	1.69684	1.68850	1.67135	1.65323
467.83	1.68420	1.67606	1.65923	1.64181
480.01	1.67931	1.67131	1.65466	1.63733
508.60	1.66974	1.66187	1.64541	1.62842
533.85	1.66286	1.65506	1.63877	1.62192
589.31	1.65139	1.64362	1.62761	1.61115

C. Bergholm gave 1.668 at -20°; 1.651 at 0°; 1.635 at 20°; and 1.616 at 41.5°. L. Lorenz found for the vap. of carbon disulphide 1.1478 for $\lambda=0.589\mu$; and 1.1457 for $\lambda=0.671\mu$; E. Mascart gave 1.1485 for $\lambda=0.589\mu$. Observations were also made by P. L. Dulong, M. Croullebois, J. Kanonnikoff, etc., on the refractive index of carbon disulphide vap. Measurements on the refractive index of binary mixtures of carbon disulphide with ether were made by C. Forch; with methylal by J. von Zawidzky; with acetone and chloroform by A. Beytheim and R. Hennicke, J. von Zawidzky, and E. E. Sundwik. S. Procopiu studied the effect of suspended crystalline particles on the birefringence of carbon disulphide. The dispersion of carbon disulphide has been studied by H. Rubens, F. F. Martens, and E. Flatoff. There is anomalous dispersion with $\lambda=326-335\mu$. A. G. Ganesan, and C. V. Raman and K. S. Rao studied the scattering and extinction of light in liquid carbon disulphide. W. W. Coblentz⁸ studied the transmission spectrum and refraction in the ultra-red; and V. Henri, the absorption spectrum; N. K. Sethi, the interference bands of liquid carbon disulphide; W. H. Keesom and J. de Smedt, the diffraction rings produced in carbon disulphide by X-rays; and S. Procopiu, the depolarization of light by carbon disulphide containing particles in suspension; and R. Gans, the Tyndall effect. T. M. Lowry considers that the sp. inductive capacity and the index of refraction give no evidence of internal ionization in the molecule. A. S. Ganesan studied the **scattering of light** by carbon disulphide.

The **electromagnetic rotation** of the plane of polarized light, has been measured by E. Verdet, who found when the value for the *E*-line is unity at 25°, 17.07 for the *G*-line; for the *F*-line, 1.234; for the *D*-line, 0.768; and for the *C*-line, 0.592. The subject has been investigated by A. de la Rive, A. Haagen, E. O. Hulbert, A. Kündt and W. C. Röntgen, and E. Bichat. J. E. H. Gordon obtained 0.05238 for the *H*-line at 13°. For the *Na*-line, Lord Rayleigh gave 0.04900 at 18°;

G. Quincke, 0.04409 (21.06°); A. Köpsel, 0.04199 (18°); E. Becquerel, 0.04341 (0°); and J. W. Rodger and W. Watson, at θ° , 0.04347(1—0.001696 θ). Carbon disulphide, unlike other liquids hitherto examined, was found by A. Colton and H. Mouton to have a negative **magnetic double refraction**. The **electric double refraction** was studied by C. F. Hagenow, C. Bergholm, G. W. Elmén, and W. König. N. Lyon and F. Wolfram measured the effect of temp. between 18° and —78.5° on the electrical double refraction. Kerr's constant was measured by G. Quincke, and O. D. Tauern; the latter gave 30.42×10^{-8} for Na-light. C. Bergholm, and M. Panthénier investigated the temp. coeff. of the electro-optical Kerr's effect; and L. Ebert, the dielectric polarization. The **absorption spectrum** of the liquid in the visible and ultra-violet regions was examined by F. F. Martens,⁹ J. Pauer, and W. Spring; and in the ultra-red, by H. Rubens; the absorption spectrum of the vap. in the visible and ultra-violet was examined by J. Pauer, G. Bruhat and M. Panthénier, and J. Dewar and G. D. Liveing; and in the ultra-red by E. von Bahr. J. Pauer, F. F. Martens, and E. Flatoff examined the absorption spectrum of soln. of carbon disulphide. R. D. Kleeman investigated the ionization of the vap. by secondary γ -rays. M. Ishino and B. Arakatsu found that negatively charged sulphur atoms are produced by the action of α -rays in the positive-ray tube. W. H. Keesom and J. de Smedt studied the diffraction of **X-rays** in the liquid. K. T. Compton calculated the **ionizing potential** at 3.57 volts. J. Müller and C. H. L. von Babo studied the fluorescence of the flame of burning carbon disulphide.

According to T. Sidot,¹⁰ metals like silver, aluminium, and iron are electrified by friction with carbon disulphide. L. Bleekrode found the liquid to have a very low **electrical conductivity**; and M. Saïd-Effendi gave 0.055 for the conductivity when that of water is unity. G. di Ciommo gave for the **specific resistance** of carbon disulphide 1.2×10^{12} rec. ohms. Many others have made observations on this subject. Carbon disulphide was found by M. Lapschin and M. Tichanowitsch not to be decomposed by the current from 950 Bunsen's cells. A. C. Becquerel found that when an aq. soln. of carbon disulphide is electrolyzed, sulphuric acid and carbon dioxide appear at the positive pole, and hydrogen sulphide and hydrocarbons at the negative pole. J. Hopkinson¹¹ found the **dielectric constant** of liquid carbon disulphide to be 2.61 for $\lambda = \infty$; L. Kahlenberg and R. B. Anthony gave 2.63 at 23.5; and A. Francke, 2.63. P. Drude obtained 2.64 at 17° for $\lambda = 73$ cms. K. Tangl gave 2.626 at 20°; and C. Bergholm, 2.74 at —26°; 2.676 at 0°; 2.626 at 20°; and 2.573 at 41.5°. K. Bädcker gave 1.00239 for the dielectric constant of the vap. at 100°, and I. Klemencic, 1.00905 at 0° and atm. press. P. Walden and co-workers, and W. H. Martin studied this subject; H. Isnardi measured the effect of temp., and F. Waibel, the effect of press. on the dielectric constant of carbon disulphide. M. Grützmacher measured the dielectric constant of mixtures of carbon disulphide with carbon tetrachloride, and with benzene, and also that of the components of the binary mixtures. For the **magnetic susceptibility**, G. Meslin¹² gave -0.59×10^{-6} mass units; S. Henrichsen, -0.74×10^{-6} vol. units at 20°; H. du Bois, -0.82×10^{-6} vol. units at 15°; and G. Quincke, -0.76×10^{-6} vol. units at 19°.

§ 42. The Chemical Properties of Carbon Disulphide

The decomposition of carbon disulphide by heat has been previously discussed. H. Buff and A. W. Hofmann said that carbon disulphide vap. is slowly decomposed by a red-hot, electrically-heated, platinum wire. L. Playfair¹ said that carbon disulphide is not decomposed when passed over red-hot pumice or charcoal. H. B. Baker said that the vap. decomposes between 200°–218°. H. B. Dixon and E. J. Russell observed that a prolonged heating is necessary at 230° before the slightest evidence of any decomposition of the disulphide can be detected, and no change is perceptible when carbon disulphide is passed through a tube at 400°; at a red heat, however, carbon disulphide was found by M. Berthelot to be resolved into its elements. In the presence of carbon, said W. Stein, the amount decomposed at a red heat is very small, and consequently, an excess of carbon is used when carbon disulphide is being prepared. J. H. van't Hoff showed that carbon disulphide, being an endothermal compound, fits in with his rule that a rise of temp. favours those substances formed with an absorption of heat. For an endothermal compound, $C + 2S - CS_2 = 26$ Cals., carbon disulphide is fairly stable. T. E. Thorpe showed that when a small quantity of mercuric fulminate is detonated in the vap. of carbon disulphide, sulphur and carbon are formed, but not by the mechanical shock which attends the explosion of gunpowder, etc. In accord with M. Berthelot's theory:

The shock of the explosion communicates to the layer of the gaseous mols. in immediate proximity to the fulminate an enormous active force, whereby the mol. edifice is shaken to pieces, and the initial active force is augmented to a degree corresponding to the heat evolved by the decomposition of the gas. A new shock is thereby produced in the next layer, and the action is repeated and so propagated until the molecular system is completely destroyed.

According to O. Loew,² when carbon disulphide is exposed for many months to sunlight, while protected from air, it decomposes, forming sulphur and a brown sulphide, C_nS_n . T. Sidot, and S. Kern made observations on the decomposition

of carbon disulphide when exposed to light. H. B. Dixon and E. J. Russell, B. von Lengyl, and J. Jamin and G. Manuvrier, likewise observed the decomposition of the liquid in the light from an electric arc. G. Bruhat and M. Pauthenier observed that carbon disulphide in a quartz cell deposits sulphur when exposed to the light from a mercury arc-lamp. The long-wave limit of decomposition was $\lambda=366\mu$. A. W. Hofmann found that carbon disulphide vap. is not decomposed by electric sparks. S. M. Losanitsch found that under the influence of the silent discharge, carbon disulphide vap. is converted into a polymeride, $(CS_2)_n$, and an almost black substance, which decomposes into its components when heated. A mixture of carbon disulphide and hydrogen under the influence of the silent discharge furnishes a brown substance, $C_3H_2S_6$, which M. Berthelot described as a compound, $C_2H_2S_4$. The action of heat on a mixture of carbon disulphide and hydrogen was studied by M. Berthelot, A. Cossa, and A. V. Harcourt; R. Witzeck investigated the heating of the mixture in a sealed tube at 250° – 370° . If treated with zinc and hydrochloric acid, A. Girard, and A. Gawalowsky reduced carbon disulphide to trimolecular thioformaldehyde, $(CH_2S)_3$. A. Mittasch found that if the mixed vapours are passed over heated nickel, mercaptan products are obtained. According to E. V. Evans and H. Stanier, carbon disulphide vapour mixed with coal-gas and passed over heated nickel is reduced, and the main reaction is symbolized: $CS_2 + 2H_2 = C + 2H_2S$. The nickel is converted into subsulphide which acts as a cyclic catalyst. The presence of thoria, alumina, or chromic oxide acts as a promotor. The reaction is utilized in C. Carpenter and E. V. Evans' system of purifying coal-gas from carbon disulphide. G. Just studied the solubility of hydrogen in carbon disulphide.

Carbon disulphide very readily inflames in air, and burns with a blue flame, according to W. A. Lampadius;³ or a white and purple-red flame, according to L. N. Vauquelin and P. J. Robiquet. J. J. Berzelius and A. Marcet exploded a mixture of carbon disulphide and oxygen by an electric spark, and obtained sulphur dioxide and carbon dioxide as products of the combustion when the supply of oxygen is great enough, but if the supply of oxygen be small, carbon monoxide is produced as well. According to G. R. Stewart and J. S. Burd, in the combustion of mixtures of 2.5–4.0 per cent. of carbon disulphide and air, from 40–60 per cent. of the carbon disulphide is oxidized according to the equations, $CS_2 + 3O_2 = CO_2 + 2SO_2$; from 25–35 per cent. follows the reaction, $2CS_2 + 5O_2 = 2CO + 4SO_2$; the remainder is unchanged. Sulphur trioxide does not seem to be formed. With a mixture containing 2.5 per cent. of carbon disulphide, the resulting gases contain about 15 per cent. of oxygen, 1 per cent. of carbon dioxide, usually less than 1 per cent. of carbon disulphide and carbon monoxide, and about 4 per cent. of sulphur dioxide. H. B. Baker showed that thoroughly dried vap. of carbon disulphide mixed with dried oxygen explodes just as readily as when moisture is present. A. Pedler found the heat developed during the explosion of a mixture of air and oxygen is so great that some nitrogen is oxidized, and the nitrogen oxide combines with the sulphur dioxide so that the gaseous product of the explosion occupies a less vol. than corresponds with $CS_2 + 3O_2 = CO_2 + 2SO_2$. G. S. Thrupin observed that carbon disulphide undergoes a slow combustion when heated with air or oxygen, forming a reddish-brown solid, which N. Smith found to have the composition $C_{16}H_8O_4S_8$. H. B. Baker concluded that combustion must be preceded by decomposition into carbon and sulphur, and suggests as a possible explanation of the combustion of pure carbon disulphide that, in this nascent state, carbon and sulphur may combine with oxygen, whether dry or not. H. B. Dixon and E. J. Russell found that if a stream of air and oxygen be passed over carbon disulphide, and the mixture flows through a tube at 200° , there is a gentle phosphorescent combustion resulting in the formation of sulphur dioxide and the condensation of a reddish-brown volatile substance. They found no signs of the resolution of carbon disulphide into its elements prior to combustion either when the gases are passed through a steady flame, as in A. Smithells' separator, or at the

high temp. of the explosion wave. When the gases are exploded over mercury, a black deposit may be formed, but this is finely divided mercury sulphide. A. Laffite showed that the spectrum of an exploding mixture of carbon disulphide and oxygen is continuous. The rate of explosion, in metres per second, with mixtures containing one molar proportion of carbon dioxide and n molar proportions of oxygen, is:

n	1	1.5	2	3	4	5	6
Rate explosion	1592	1702	1754	1802	1753	1732	2640

The maximum velocity is thus obtained when sufficient oxygen is present to burn the carbon and sulphur respectively to their dioxides. The explosion wave is not propagated in the mixture $CS_2 + \frac{1}{2}O_2$. According to H. le Chatelier and Q. Boudouard, the lower limit of inflammability is with mixtures containing 0.063 gm. of carbon disulphide per litre of air. H. B. Dixon and E. J. Russell said that the mixture richest in carbon disulphide which can be made to detonate or give the explosion wave contains one vol. of oxygen to 1.5 vols. of carbon disulphide vap.; and in the other direction the limit is not so quickly reached, for mixtures containing 6-7 vols. of oxygen and one vol. of carbon disulphide vap. still detonate. They found that the reaction which takes place when carbon disulphide is exploded with oxygen could not be expressed by any simple equation: (a) When excess of oxygen is used, the products are carbon dioxide, sulphur trioxide, sometimes free sulphur; and in the explosion wave, carbon monoxide, carbonyl sulphide, and unchanged carbon disulphide. (b) With an insufficient quantity of oxygen, the products are carbon dioxide, sulphur dioxide, carbon monoxide, carbonyl sulphide, and carbon disulphide. When the amount of oxygen is successively diminished, the quantity of sulphur dioxide falls off, and that of the carbon monoxide, carbonyl sulphide, and unchanged carbon disulphide increases. (c) Even with small amounts of oxygen, there is always a division of the oxygen between the carbon and sulphur. Using a mixture, $CS_2 + \frac{1}{2}O_2$, only a portion of the carbon disulphide takes part in the reaction. P. Laffite studied the formation of the explosion wave in mixtures of oxygen and carbon disulphide. H. T. Tizard and D. R. Pye noted the formation of hydrogen sulphide when a mixture of carbon disulphide vap. and moist air is exploded: $CS_2 + 2H_2O = 2H_2S + CO_2$. When burnt in the Smithells' separator, the phenomena are altogether different from those observed in the explosions. The interconal gases consist of nearly equal vols. of sulphur dioxide and carbon monoxide, together with sulphur vap. and some unchanged carbon disulphide, and small quantities of carbonyl sulphide and carbon dioxide. W. A. Lacapadius said that carbon disulphide takes fire in air below 100° , and it is said by M. Berthelot to be more inflammable than ether. J. J. Berzelius and A. Marccet estimated the ignition temperature to be "just above the b.p. of mercury"—i.e. 357° - 358° . E. Frankland gave 149° ; R. Böttger, 228° ; H. B. Baker gives the ignition point of carbon disulphide mixed with oxygen as 258° - 260° . G. S. Turpin states that when carbon disulphide is mixed with ten times its vol. of oxygen, the slow combustion develops into ignition at 160° ; and when mixed with ten times its vol. of air it ignites at 290° . H. B. Dixon and E. J. Russell stated that the change from the slow phosphorescent combustion to actual ignition is not sharp, and that carbon disulphide cannot be said to have any definite ignition point. In some cases they ignited a mixture of oxygen and carbon disulphide below 180° , at other times no ignition occurred at 230° . E. Berl and H. Fischer gave for the explosion limits of mixtures of air and carbon disulphide vap. in a glass globe 27 mm. diameter, 2.22 and 31.20 per cent. carbon disulphide, and in a glass globe 48 mm. diameter, 2.69 and 30.20 per cent. In an iron vessel at ordinary temp. 3.38-29.20, and at 100° , 1.35-33.10 per cent. According to T. Wulf, E. Sell, B. Delachanal and A. Mermet, and M. Tiffereau a mixture of carbon disulphide vap. with oxygen burns with a very bright blue flame which is particularly rich in actinic rays, and is applicable to photographic work. H. C. C. Dibbitts studied the spectrum of the carbon disulphide flame. According to E. Pringsheim:

The temp. of the flame of carbon disulphide can be made very low; the light is not brilliant but is distinctly blue and can readily be seen in a darkened room. The temp. is low and the amount of heat generated is so small that one can hold one's finger in the flame indefinitely without feeling more than a moderate sensation of heat. . . . The carbon disulphide flame was regulated so that it just burned; the flame was very long and pointed at shape. Repeated measurements with a thermocouple, at the hottest portion of the flame just below the point, gave temp. between 114° and 146°. We can therefore say definitely that this flame continues burning at temp. below 150°, below the ignition temp. of the inflammable mixture which gives rise to the flame. The light emitted by this flame has a very considerable photographic action. . . . The flame gives a continuous spectrum which is much weaker in the red part than in the blue and violet; it is very like the spectrum obtained when sulphur or hydrogen sulphide burns in the air. There can be no doubt but that we are dealing with gases which luminesce in consequence of chemical reactions and not in consequence of high temp.

According to M. Berthelot, a mixture of air and carbon disulphide vap. may be exposed to diffused daylight for a year without any change taking place, but if exposed to bright sunlight, some reaction takes place in an hour or two, and a yellowish-white substance is deposited which contains sulphur, carbon, and oxygen, whilst carbon monoxide and carbon dioxide are also formed, and remain mixed with the residual oxygen and the nitrogen. No nitrogen enters into combination, and in this respect the action of light differs from that of the silent electric discharge. The most important point about the reaction is that the light has no effect until it reaches a certain and somewhat high intensity; it is, therefore, analogous to the many reactions that do not take place below a particular temp. J. J. Berzelius and A. Marcet said that when carbon disulphide is kept under water for a long time in vessels containing air, it acquires a yellow colour, and is partially oxidized to sulphur and carbon dioxides. According to O. Loew, the slow action of water on carbon disulphide in sunlight produces a little formic acid; and when carbon disulphide is heated with water and iron filings in a sealed tube at 100°, ferrous formate, iron sulphide, carbon dioxide, and two sulphur compounds are formed. N. Smith found that the slow combustion of carbon disulphide in the presence of water vap., at 175°-180°, furnishes a product with the composition $C_{16}H_6O_4S_8$. This compound has acidic properties, and an ammonium salt and a silver salt, $Ag_2C_{16}H_6O_4S_8$, were prepared. L. Gurwitsch observed that the reaction $CS_2 + 2H_2O = 2H_2S + (CO_2)$ is catalyzed by partially dehydrated alumina hydrate. G. Chancel and F. Parmentier measured the solubility, S grms. per 100 c.c. of soln., of carbon disulphide in water, and found

	0°	10°	15°	20°	25°	30°	40°	45°	48°
S . .	0.204	0.194	0.187	0.179	0.169	0.155	0.111	0.070	0.014

A. Rex gave at 0°, 10°, 20°, and 30° respectively 0.258, 0.239, 0.217, and 0.195 grm. of carbon disulphide per 100 grms. of water. According to W. Heiz, at 22°, 100 c.c. of water dissolve 0.174 c.c. of carbon disulphide, and the vol. of the soln. is 100.208 c.c., and the sp. gr. 0.9981; reciprocally, 100 c.c. of carbon disulphide dissolve 0.961 c.c. of water and the vol. of the soln. is 100.961, and the sp. gr. 1.253. The solubility of carbon disulphide in water was also measured by E. M. Pélégot, W. T. Page, F. Sestini, M. Ckandi-Bey, and J. B. A. Dumas. P. Villard said that no hydrated carbon disulphide can be formed at ordinary press., but at 75 atm. press. crystals of a hydrate are formed between 0° and 1°. M. Berthelot reported $2(CS_2 \cdot 3H_2O)$; M. Ballo, $(CS_2 \cdot H_2O)$; and E. Duclaux, $2CS_2 \cdot H_2O$. A. Marcet, V. Wartha, and F. P. Venable have made observations on possible hydrates. According to C. Caigniard de la Tour, when the temp. of a mixture of water and carbon disulphide in a sealed glass tube is gradually raised, the mixture becomes turbid, then clear. The colour at first is greenish but gradually darkens, becoming at last nearly black. The carbon disulphide rises to the top of the water and then passes into the state of vap. On cooling, the green colour of the water changes to yellow, and the undecomposed carbon disulphide again sinks to the bottom. F. Schlagdenhaufen obtained a mixture of carbon dioxide and hydrogen sulphide by heating

the mixture of water and carbon disulphide in a sealed tube at 150° . M. Berthelot found that a mixture of the vap. of carbon disulphide and water give methane and ethylene when passed over iron or copper at a dull red-heat. At lower temp., said M. Witzcek, some carbonyl sulphide is formed. By heating the mixture of water and carbon disulphide under press., P. Schützenberger obtained crystalline carbon hydrosulphide, $\text{CS}_2 \cdot \text{H}_2\text{S}$.

According to H. Moissan,⁴ the vap. of the carbon disulphide inflames when in contact with cold fluorine; and if a current of fluorine is passed into the liquid disulphide each bubble of gas becomes luminous. A mixture of carbon and sulphur fluorides is produced, but no free carbon. J. J. Berzelius and A. Marcet observed that carbon disulphide is decomposed by chlorine. According to B. Rathke, dry chlorine at ordinary temp. reacts very slowly with carbon disulphide, forming sulphur chloride, carbon tetrachloride, and some thiocarbonyl chloride. A. Mouneyrat found that aluminium chloride acts as a catalyst on the reaction; B. Aronheim, molybdenum pentachloride; and A. W. Hofmann, antimony pentachloride. In the presence of iodine, P. Klasan, and B. Rathke found that chlorine reacts with carbon disulphide producing sulphur chloride, carbon tetrachloride, and perchloromethyl mercaptan, CCl_3SCl . R. Weber also obtained red crystals of sulphur chloriodide, ICl_3SCl_4 . P. Klasan investigated the different stages in the reaction between chlorine and carbon disulphide. H. Müller investigated the action of chlorine on boiling iodiferous carbon disulphide. Moist chlorine was found by H. Kolbe to act more rapidly than the dry gas, and he obtained trichloromethyl sulphuryl chloride, $\text{CCl}_3\text{SO}_2\text{Cl}$, as a product of the reaction, and B. Rathke, and M. Albrecht obtained perchloromethylmercaptan, or thiocarbonyl tetrachloride, CCl_3SCl . According to H. Kolbe and A. W. Hofmann, when a mixture of dry chlorine, and the vapour of carbon disulphide is passed through a red-hot tube, sulphur chloride and carbon tetrachloride are formed. C. Hell and F. Urech obtained an oil, carbon disulphotetrabromide, CS_2Br_4 , when dry bromine is allowed to stand in contact with carbon disulphide for several days, or when a mixture of carbon disulphide and bromine water is allowed to stand for some time. M. I. Konowaloff and W. Plotnikoff obtained a number of compounds of carbon disulphide with bromine, aluminium bromide, ethyl bromide, bromoform, etc.—e.g. $\text{CS}_2\text{Br}_4 \cdot \text{AlBr}_3$; $\text{CS}_2\text{Br}_4 \cdot 2\text{AlBr}_3$; $\text{CS}_2\text{Br}_4 \cdot \text{AlBr}_3 \cdot \text{CHBr}_3$; $\text{CS}_2 \cdot 2\text{AlBr}_3 \cdot 2\text{C}_2\text{H}_5\text{Br}$; $\text{CS}_2\text{Br}_2 \cdot \text{AlBr}_3 \cdot \text{C}_2\text{H}_5\text{Br}$; $\text{CS}_2 \cdot \text{AlBr}_3 (\text{CH}_2\text{Br} \cdot \text{CH}_2\text{Br})$; and $\text{CS}_2 \cdot \text{AlBr}_3 (\text{CH}_3 \cdot \text{CHBr}_2)$. F. Urech, and J. Haebermann obtained carbon tetrabromide by the action of bromine on carbon disulphide in the presence of water or alkali-lye, and exposed to sunlight. T. Bolas and C. E. Groves found that when a mixture of carbon disulphide and bromine is heated for a long time in a sealed tube at 180° – 200° , carbon tetrabromide is formed. R. Höländ, and T. Bolas and C. E. Groves found that the reaction is accelerated by the presence of iodine, or by the bromides of antimony, arsenic, bismuth, gold, etc.; and A. Mouneyrat, by aluminium chloride. R. Weber showed that iodine trichloride acts like chlorine in the presence of iodine. J. B. Hannay represented the reaction: $4\text{CS}_2 + 6\text{ICl}_3 = 2\text{CCl}_4 + 2\text{SCl}_2 + 3\text{S}_2\text{Cl}_2 + 3\text{I}_2$; it was also studied by R. Weber. The solubility of bromine in carbon disulphide has been investigated by H. Arctowsky—*vide* bromine. The solubility of iodine in carbon disulphide, and the partition of bromine and of iodine between water and carbon disulphide was measured by M. Berthelot and E. Jungfleisch, E. Angelescu and D. Dumitrescu, and A. A. Jakowkin—*vide* iodine. The sp. ht. of soln. of iodine and of bromine in carbon disulphide were measured by J. C. G. de Marignac. E. Drechsel found that carbon disulphide is not attacked by hydriodic acid in a sealed tube at 150° ; M. Berthelot studied the action of carbon disulphide and hydrogen iodide at a red heat and noted that methane is produced. A. J. Balard found that the vap. of carbon disulphide explodes when in contact with chlorine monoxide, forming carbon dioxide, sulphuric acid, sulphur chloride, and chlorine; P. Schützenberger found that with chlorine monoxide, carbonyl and thionyl chlorides are produced. A. J. Balard found that with a soln. of hypochlorous

acid, chlorine, carbon dioxide, and sulphuric and hydrochloric acids are produced. J. C. Ritsema represented the action of alkali hypochlorite by $8\text{KOC}l + \text{CS}_2 + 6\text{KOH} = 2\text{K}_2\text{SO}_4 + \text{K}_2\text{CO}_3 + 8\text{KCl} + 3\text{H}_2\text{O}$. W. M. Dehn said that when carbon disulphide was treated with sodium hypobromite, the oil disappeared rapidly, and enough heat was developed to boil the unchanged carbon disulphide. When treated with different quantities of sodium hypobromite, soln. were obtained containing sulphide, sulphite, sulphate, formate, and carbonate. An excess of sodium hypobromite yielded quantitatively the sulphur as sulphate. According to C. Cagniard de la Tour, if a mixed aq. soln. of potassium chlorate and carbon disulphide is heated in a sealed tube, the liquid effervesces and some sulphur is formed. On opening the cooled tube, a gas escapes and the water has an acid reaction. A. Ditte represented the reaction between iodic acid, water, and carbon disulphide by the equations: $2\text{HIO}_3 + \text{CS}_2 = \text{I}_2 + \text{CO}_2 + \text{H}_2\text{SO}_4 + \text{S}$; and $2\text{HIO}_3 + 2\text{CS}_2 + 2\text{H}_2\text{O} = 2\text{CO}_2 + 2\text{HI} + \text{H}_2\text{SO}_4 + \text{H}_2\text{S} + 2\text{S}$. F. Schlegdenhauffen found that iodic acid, bromic acid, and the iodates, bromates, and chlorates, and hypochlorites oxidize carbon disulphide when heated in a sealed tube, forming hydrogen halide, a metal halide, etc. The solubility of sulphur in carbon disulphide has been studied by G. Gore,⁵ A. Cossa, H. Arctowsky, etc.—*vide* sulphur. J. J. Berzelius studied the properties of the soln. The sp. gr. of the soln. has been measured by G. J. Pfeiffer; the sp. ht. by J. C. G. de Marignac; and the refractive index by V. Berghoff, and C. Forch. The solubility of selenium in carbon disulphide was measured by E. Mitscherlich and G. Gore,—*vide* selenium. G. Gore investigated the solubility of the sulphur and selenium chlorides, bromides and iodides (*q.v.*) in carbon disulphide. According to P. Schützenberger, if a mixture of hydrogen sulphide and the vap. of carbon disulphide be passed through a tube cooled to -25° , an unstable crystalline compound, carbon hydrosulphide, $\text{CS}_2 \cdot \text{H}_2\text{S}$, is formed; and, according to M. Berthelot, if the mixture be passed over copper or iron at a dark red heat, methane and ethylene are produced. According to J. J. Berzelius, soln. of the alkali sulphides, and, according to B. Holmberg, soln. of the alkali hydrosulphides, absorb carbon disulphide and form alkali thiocarbonate, in the latter case with the development of hydrogen sulphide. According to A. Gélis, carbon disulphide unites with sodium disulphide, Na_2S_2 , to form sodium perthiocarbonate, Na_2CS_3 , with the development of heat. F. Sestini studied the solubility of carbon disulphide in liquid sulphur dioxide; he found that mixtures of sulphur dioxide and carbon disulphide, dry or moist, do not give carbon monoxide when heated. M. Albrecht found that when carbon disulphide is boiled with potassium sulphite in the presence of some alcohol potassium methyl mercaptan trisulphonate, $\text{HS.C(KSO}_3)_3$, is formed. According to A. Geuther, carbon disulphide is miscible with sulphuric acid free from water. M. Brault and A. B. Poggiale found that carbon disulphide is decomposed by cold sulphuric acid, forming sulphur and carbon; and when a mixture of the vap. of these two substances is passed through a red-hot tube, carbon monoxide, sulphur dioxide, hydrogen sulphide, and sulphur are formed. H. E. Armstrong represented the reaction at 100° between sulphur trioxide and carbon disulphide by the equation $\text{SO}_3 + \text{CS}_2 = \text{S} + \text{SO}_2 + \text{COS}$. J. Dewar and G. Cranston found that chlorosulphonic acid reacts in an analogous manner.

M. Berthelot⁶ noted that under the action of the silent discharge a mixture of carbon disulphide vap. and argon, in the presence of the liquid at 20° , showed the argon to be absorbed, and he believed that combination occurred. He also studied the absorption of helium and nitrogen by carbon disulphide. G. Just measured the solubility of nitrogen in the liquid. According to J. J. Berzelius and A. Marcet, dry ammonia is slowly absorbed by carbon disulphide producing a substance whose composition depends on the conditions of the experiment. W. C. Zeise said that no ammonium carbonate is formed, but the dark brown liquid which is produced contains ammonium thiocarbonate and thiocyanate. N. A. E. Millon found that if evaporated in moist ammoniacal air, the vap. is oxidized, forming a dense cloud. A. Laurent, P. Tcherniac and H. Gunzburg, H. Debus, M. Freund and G. Bachrach,

G. J. Mulder, and C. H. van Zouteveen also studied the reaction in aq. or alcoholic soln. Carbon disulphide dissolves abundantly in alcohol sat. with ammonia gas, and, added W. C. Zeise:

The soln. remains alkaline, even with a large excess of carbon disulphide. Even when protected from the air it soon turns yellow, then brown, and smells of hydrogen sulphide. After the lapse of from 10 to 30 mins., it deposits yellow feathery crystals of ammonium thiocarbonate; then more shining crystals of ammonium thiocyanate are formed, while those of the carbonatohydrosulphide diminish in quantity. The alcoholic liquid still retains very large quantities of ammonium thiocyanate and hydrosulphide, which, on distillation or exposure to the air, are resolved into ammonium hydrosulphide which escapes, sulphur which crystallizes out, ammonium thiocyanate which remains in soln. In the first stage of the reaction three mols. each of ammonia and carbon disulphide react to form a mol. each of ammonium thiocarbonate and thiocyanate; the decrease in the proportion of the former, the increase in the proportion of the latter, and the formation of ammonium sulphide are probably due to a reaction between two mols. of thiocarbonate and one mol. of ammonia, to form three mols. of hydrogen sulphide, and one of thiocyanic acid.

According to A. Goldberg, if carbon disulphide and alcoholic ammonia are heated at 60° under press., one-half the sulphur is converted into ammonium sulphide, and he attempted to apply the reaction in quantitative analysis. At a red-heat, ammonia and carbon disulphide vap. were stated by F. Schlagdenhauffen to react. According to G. Inghilleri, when carbon disulphide and ammonium carbonate are heated in a sealed tube at 100°-110°, ammonium dithiocarbonate is produced; at 120°-130°, ammonium thiocyanate; and at 160°, an almost quantitative yield of thiocarbamide is obtained; if the mixture in alcoholic soln. is heated on a water-bath, an almost quantitative yield of ammonium thiocyanate is obtained. F. Beilstein and A. Geuther found that when the vap. of carbon disulphide is passed over heated sodium amide, sodium thiocyanate is formed. C. A. L. de Bruyn studied the reaction between hydroxylamine and carbon disulphide, which is attended by the separation of sulphur. A. Goldberg attempted to separate the sulphur from a mixture of carbon disulphide and benzene by the hydroxylamine reaction. T. Curtius and K. Heidenreich found that carbon disulphide and hydrazine hydrate, in the cold, form dithiocarbazine acid, $H_2N.NH.CS.SH$; and M. Busch boiled a mixture of carbon disulphide with hydrazine and alcoholic soln. of potassium hydroxide and obtained thiodiazoldithio-. A. W. Browne and A. B. Hoel showed that the vap. of carbon disulphide is irreversibly and quantitatively absorbed by aq. soln. of potassium or sodium azide at room temp., and the use of the reagent as an absorbent in gas analysis was discussed by A. J. Currier and A. W. Browne.

The character of the flame furnished by a burning mixture of carbon disulphide vap. and nitric oxide has been indicated in connection with the oxygen and carbon disulphide flame. According to L. H. Friedberg, nitric acid at ordinary temp. has no action on carbon disulphide; and, according to S. Cloez and E. Guignet, there is no reaction with the boiling acid; but, according to M. Tiffereau, the carbon disulphide is oxidized at ordinary temp. if the mixture be exposed to sunlight. F. Schlagdenhauffen found that the mixed vap. of carbon disulphide and nitric acid passed through a red-hot tube form sulphuric acid and nitrous fumes. The vap. of carbon disulphide also reduces the nitrites. According to F. Schlagdenhauffen and M. Bloch, when an excess of aqua regia is distilled with carbon disulphide—either immediately after mixing or after contact for some hours—red nitrous fumes and unattacked carbon disulphide first pass over, followed by a very volatile substance, which can be condensed by using a freezing mixture of ice and salt; it proved to be trichloromethylsulphurous chloride, $SO(OC_2H_5)_3Cl$.

The solubility of phosphorus in carbon disulphide has been measured by A. Vogel, H. Giran, etc.—vide phosphorus. J. C. G. de Marignac measured the sp. ht. of the soln., and V. Berghoff, the indices of refraction. M. Berthelot found the vap. of carbon disulphide and phosphine produce methane and ethylene when passed over copper or iron at dull redness. According to L. P. Cailliet and M. Bordet, when a mixture of dry, phosphine and carbon disulphide is compressed,

no compound is formed, but in the presence of a little water, a white crystalline solid is deposited which dissociates when the temp. is raised, or the press. relieved. According to E. Drechsel, carbon disulphide and phosphonium iodide react in an iron tube at 150° , forming trimethyl phosphine hydriodide; and if an excess of carbon disulphide is used, H. Jahn found that methane is produced. A. W. Hofmann found that triethylphosphine unites with carbon disulphide, forming red prismatic crystals, $P(C_2H_5)_3 \cdot CS_2$. The solubilities of the chlorides, bromides, and iodides of phosphorus, arsenic, and antimony in carbon disulphide have been measured by G. Goye. L. Carius, and B. Rathke studied the action of phosphorus pentachloride and obtained the carbonyl chloride, etc. F. Schlagdenhauffen found that when carbon disulphide and arsenious acid or arsenic acid and the salts of these acids are heated in a sealed tube, arsenic sulphide is formed. According to A. W. Hofmann, carbon disulphide reacts vigorously with antimony pentachloride, forming carbon tetrachloride, antimony trichloride, sulphur, and sulphur chloride. B. Aronheim, A. Husemann, A. Bertrand and E. Finot also studied the reaction. H. Moissan found that the vap. of carbon disulphide attacks boron at a bright red heat, forming boron sulphide; he also found boron trioxide to be soluble in carbon disulphide. According to E. Frémy, boron trioxide is converted into the sulphide when heated in the vap. of carbon disulphide.

The adsorption of the vap. of carbon disulphide by carbon has been studied by J. Hunter,⁸ A. Eloart, J. N. Bronsted and V. K. la Mer, and J. Driver and J. B. Firth. According to S. M. Losanitsch, when the vap. of carbon disulphide and ethylene are exposed to the silent electric discharge, brownish-yellow carbon ethylene disulphide, $5CS_2 \cdot 2C_2H_4$, is formed; with acetylene, black carbon acetylene disulphide, $3CS_2 \cdot 2C_2H_2$, is produced; and with carbon monoxide, brown carbon carbonyl disulphide, $3CS_2 \cdot 2CO$, is obtained. G. Just measured the solubility of carbon dioxide in carbon disulphide. E. Schöne said that carbon dioxide and disulphide form carbon monoxide and sulphur when passed through a red-hot tube; and C. Winkler said that some carbonyl sulphide is formed, particularly if the mixed gases are passed over heated platinized asbestos. The main reactions with carbon dioxide are represented: $CO_2 + CS_2 = 2CO + 2S$, and $CO + S + H_2O = CO_2 + H_2S$; the secondary reactions: $CO + S = COS$; and $H_2S = H_2 + S$. *T. Carnelley found that when a mixture of vap. of carbon disulphide and ethyl alcohol is passed over copper at a dull red-heat, carbonyl sulphide, etc., are formed. C. Tuchschnidt and O. Follenius studied the solubility of carbon disulphide in c.c. per 100 c.c. of aq. soln. of ethyl alcohol at 17° , and found

Alcohol	100	98.15	93.54	81.12	48.40	47.90 per cent.
CS_2	90	132	70	30	2	0 c.c.

F. Guthrie found a soln. of ethyl alcohol with 94.94 per cent. of carbon disulphide remains clear down to -18.4° ; with 89.54 per cent. CS_2 , it becomes turbid at -14.4° ; with 79.96 per cent. CS_2 , it becomes turbid at -16.1° ; with 65.11 per cent. CS_2 , it becomes turbid at -17.7° ; and soln. with 59.58 to 29.92 per cent. CS_2 , remain clear down to -20° . E. C. McKelvy and D. H. Simpson studied the solubility in ethyl alcohol and in methyl alcohol. V. Rothmund found that with methyl alcohol two layers are formed, and that the percentage amounts of carbon disulphide in the two layers are:

	10°	20°	25°	30°	35°	40.5°
CH_3OH layer	45.1	50.8	54.1	58.4	64.0	80.5
CS_2 layer	98.3	97.2	96.4	95.5	93.5	80.5

The critical soln. temp. is 40.5° . J. H. Schüller, J. C. G. de Marignac, A. Winkelmann, L. Frank, F. Guthrie, and F. D. Brown have studied the properties of mixtures of carbon disulphide with ether, chloroform, benzene, and carbon tetrachloride—*vide supra*. For the action of alcohols in the presence of alkalies—*vide infra*, the xanthogenates. Numerous reactions of carbon disulphide with organic compounds have been studied. According to C. Liebermann, paraffin can

absorb three times its weight of carbon disulphide, and has accordingly been recommended as an absorbent for the disulphide in desiccators. E. Frémy and A. Colson found that at a high temp. carbon disulphide reacts with **silicon**, forming silicon sulphide.

It will be observed that carbon disulphide has marked **solvent qualities**; it dissolves nitrogen chloride, hydrogen sulphide and persulphide, bromine, iodine, sulphur, selenium, arsenic, antimony, the chlorides of phosphorus, sulphur, selenium, arsenic, antimony, tin, titanium, sulphur dioxide, nitrogen oxides, carbonyl sulphide, etc. It also dissolves fats, oils, ethereal oils, resins, colouring agents, camphor, caoutchouc, gutta-percha, wax, paraffin, etc.—F. Schlagdenhauffen, G. Gore, etc.

According to J. J. Berzelius,⁹ heated **potassium** takes fire in the vap. of carbon disulphide, and burns with a reddish flame, and becomes covered with a black crust, which dissolves in water with the separation of carbon. According to O. Loew, when **sodium** and carbon disulphide are heated in a sealed tube at 140°–150°, sodium sulphide and *sodium thiosquicarbonate*, $\text{Na}_2\text{C}_2\text{S}_3$, are formed. The latter, with water, gives *thiosquicarbonic acid*, $\text{H}_2\text{C}_2\text{S}_3$. L. Raab obtained a product, C_5S_8 . By treating a liquid alloy of potassium and sodium with rectified carbon disulphide, T. E. Thorpe obtained a yellowish-brown powder which he said was more explosive than nitrogen iodide. Observations on the action of carbon disulphide on the alkali metals or their amalgams have been made by C. Löwig, H. Frégl, R. Hermann, C. Reichl and E. Guignet. When carbon disulphide vap. is passed over red-hot **copper** or **iron**, not sufficient to decompose it completely, it is converted into a rose-red liquid which contains carbon monosulphide and undecomposed disulphide; at the same time, the copper is converted into sulphide, and, added M. Cluzel, the sulphide is covered with a layer of carbonaceous matter, but L. J. Thénard and L. N. Vauquelin obtained no evidence supporting the latter statement. S. Kern also said that iron at ordinary temp. transforms carbon disulphide into the monosulphide; and, according to V. Merz and W. Weith, there is formed at 250°–270°, iron sulphide and a dark brown substance which is probably an iron sulphocarbide. The last-named also obtained with copper at 200°–250°, copper sulphide and a black carbon sulphide. A. Cavazzi passed the vap. of carbon disulphide over heated copper, iron, **silver**, **magnesium**, **zinc**, and **aluminium**, and obtained the metal sulphides and graphitoid carbon; no compound of carbon with sulphur was observed to be formed. According to E. Lionnet, if a strip of **tin** foil be wrapped spirally about a gold or platinum wire, and dipped in carbon disulphide, tin sulphide and colourless crystals are formed. He thought the crystals were veritable diamonds (*q.v.*). P. Schützenberger passed the vap. of carbon disulphide over **platinum** sponge at 400°–450°, and obtained a *platinum sulphocarbide*, Pt_2CS_2 .

J. J. Berzelius and A. Marcat found that the **alkaline earth oxides** are converted into sulphides and carbonates; and the former also found that **iron oxide**, **manganese oxide**, and **tin oxide** are converted into the corresponding sulphides and sulphur and carbon dioxides. Carbon disulphide is a powerful sulphurizing agent; according to E. Frémy,¹⁰ *le plus énergique qu'on connaisse*, for it readily converts the metal oxides into their sulphides. F. Schlagdenhauffen obtained the corresponding sulphides by heating **lead oxide**, **zinc oxide**, **cobalt oxide**, **antimony oxide**, iron oxide, and manganese oxide, with carbon disulphide in a sealed tube at 250°. According to E. Frémy, and F. G. Reichel, carbon disulphide vap. converts red-hot **magnesia** and **alumina** into the corresponding sulphides. A. Gautier found that when carbon disulphide is passed over red-hot **china clay** (kaolin), carbonyl sulphide, silicon sulphide, and aluminium thiosilicate are formed; while with **alumina**, **aluminium sulphide** and carbonyl sulphide are formed. H. Rose found **tantalum oxide** is likewise converted into the sulphide.

Aq. soln. of **alkali hydroxides** slowly dissolve carbon disulphide, forming alkali carbonate and thiocarbonate: $6\text{KOH} + 3\text{CS}_2 = \text{K}_2\text{CO}_3 + 2\text{K}_2\text{CS}_3 + 3\text{H}_2\text{O}$. F. Sestini

also found that by digesting carbon disulphide and an aq. soln. of an **alkali carbonate** at 60°, carbon dioxide is evolved, and alkali thiocarbonate is formed. D. Walker, and R. Sestini found that an aq. soln. of **calcium hydroxide** at ordinary temp. or at 50°, furnishes orange-yellow needles of **calcium hydroxythiocarbonate**, $\text{CaCS}_3 \cdot \text{Ca}(\text{OH})_2 \cdot 6$ (or 7) H_2O ; **barium hydroxide**, and **magnesium hydroxide**, under similar conditions, form respectively **barium** and **magnesium hydroxythiocarbonates**; but carbon disulphide does not act on **zinc hydroxide**. G. Chancel, and F. Parmentier found that when baryta-water is mixed with an aq. soln. of carbon disulphide, or with a mixture of carbon disulphide and water, very little action takes place at the ordinary temp., but if the mixture is heated an abundant precipitate of barium carbonate is formed, and the supernatant liquid becomes yellow. If the mixture is heated in sealed tubes at 100° for some time, the liquid gradually becomes colourless, and the amount of barium carbonate formed is greater than that calculated from the equation given by J. J. Berzelius, $3\text{CS}_2 + 6\text{MOH} = \text{M}_2\text{CO}_3 + 2\text{M}_2\text{CS}_3 + 3\text{H}_2\text{O}$. When carbon disulphide is heated with an excess of a somewhat dil. soln. of barium hydroxide at 100°, in sealed tubes previously filled with nitrogen, the reaction is represented by the equation: $\text{CS}_2 + 2\text{Ba}(\text{HO})_2 = \text{BaCO}_3 + \text{Ba}(\text{SH})_2 + \text{H}_2\text{O}$. If the mixture is heated in contact with air, the same proportion of barium carbonate is formed, but it is mixed with a certain quantity of barium sulphate formed by the oxidation of the hydrosulphide. F. Schlagdenhauffen investigated the action of carbon disulphide on many salts. Molten **potassium nitrate** oxidizes the vap. to carbon dioxide, nitrous fumes, potassium thiocyanate, and sulphate; **potassium nitrite** behaves similarly; and when potassium or lead nitrite and carbon disulphide are heated in a sealed tube, carbon dioxide, the metal thiocyanate, etc., are formed. E. Obach found that carbon disulphide is scarcely affected by a cold soln. of **potassium permanganate**, but, according to S. Cloez and E. Guignet, a boiling soln. is quantitatively reduced, forming sulphuric acid, and carbon dioxide. F. Schlagdenhauffen found that carbon disulphide reduces **chromic acid** and the **chromates**, the lower oxide of chromium being formed when the mixture is heated in a sealed tube; similar results were obtained with **molybdic**, **tungstic**, **vanadic**, and **titanic acids**. He also found that many **metal salts** when heated with carbon disulphide in a sealed tube to 200°–250°, in the presence or absence of water, furnish sulphides, and carbon dioxide and the acids of the salts are set free—**cuprous chloride** is but little attacked at 250°, and **cuprous iodide** is not affected at 300°. H. Müller studied the behaviour of some metal salts towards carbon disulphide.

A. C. Becquerel, and F. Wöhler studied the action of a copper plate dipping in superposed layers of carbon disulphide and an aq. soln. of **cupric nitrate**. The former said copper suboxide, the latter said cupric sulphide, is deposited in the lower part. According to G. Gore, carbon disulphide dissolves **stannic chloride** and **titanic chloride**. H. Arctowsky measured the solubility of stannic chloride in carbon disulphide at low temp.; and he also found that at 20°, 100 grms. of a sat. soln. contained 0.042 grm. of **mercuric chloride**, or 0.187 grm. of **mercuric bromide**, or 0.320 grm. of **mercuric iodide**. C. E. Linebarger also measured the solubility of the three mercuric halides in carbon disulphide. H. Arctowsky also found **mercuric nitrate** is very soluble in boiling carbon disulphide; **ferric chloride**, and **lead nitrate** are also soluble in carbon disulphide, but most other salts of the metals are insoluble. B. Aronheim studied the effect of **molybdenum chloride** on carbon disulphide.

Reactions of analytical interest.—According to A. W. Hofmann,¹¹ carbon disulphide can be quantitatively determined by passing the vap. through an ethereal soln. of triethylphosphine; and the red crystalline compound $\text{P}(\text{C}_2\text{H}_5)_3 \cdot \text{CS}_2$ dried in vacuo and weighed; according to E. Fischer, M. Busch, and C. Liebermann and A. Seyewitz, the white compound it forms with phenylhydrazine, namely, $\text{C}_6\text{H}_5 \cdot \text{NH} \cdot \text{NH} \cdot \text{CS} \cdot \text{S} \cdot \text{NH} \cdot \text{NH} \cdot \text{C}_6\text{H}_5$, can be used in a similar manner. According to G. Chancel and F. Parmentier, carbon disulphide can be estimated by heating in a sealed tube at 100° a mixture of carbon disulphide and baryta-water; barium

sulphide is formed. This is converted into barium sulphate and weighed. According to G. Denigès, when a mercuric salt is warmed with carbon disulphide, a disulphide, $\text{HgX}_2 \cdot 2\text{HgS}$, is formed as a characteristic crystalline precipitate. A. Goldberg treated carbon disulphide with aq. ammonia whereby a mixture of hydrosulphide and thiocyanate is formed: $\text{CS}_2 + 3\text{NH}_3 \rightarrow \text{NH}_4\text{HS} + \text{NH}_4\text{CNS}$. The sulphide is then titrated with ammoniacal soln. of a zinc salt. When carbon disulphide is treated with an alcoholic soln. of potassium hydroxide, potassium xanthate, $\text{KS}(\text{S} \cdot \text{OC}_2\text{H}_5)_2$, is formed. This can be estimated by titration with standard cupric sulphate as recommended by H. Macagno, E. A. Grete, O. Hehner and W. L. Carpenter, or E. P. Harding and J. Boran: $2\text{CuSO}_4 + 4(\text{KS}(\text{S} \cdot \text{OC}_2\text{H}_5)_2) = \text{Cu}(\text{S} \cdot \text{S} \cdot \text{OC}_2\text{H}_5)_2 + \text{C}_2\text{H}_5\text{O} \cdot \text{CS} \cdot \text{S} \cdot \text{S} \cdot \text{OC}_2\text{H}_5 + 2\text{K}_2\text{SO}_4$. The copper xanthate can be converted to the oxide and weighed as recommended by H. Macagno; E. S. Johnson, or M. Ragg. The xanthate can be oxidized to sulphate by titration with standard permanganate as recommended by W. Schmitz-Pumont; with standard hydrogen dioxide as recommended by J. Petersen, or D. Stravrinus; or with potassium iodide after the soln. has been neutralized with sodium carbonate as recommended by L. G. Radcliffe, M. Gastine, or E. Rupp and L. Krauss.

The physiological action of carbon disulphide.—Carbon disulphide is a blood poison and is fatal to all forms of animal life.¹² Observations on animals show that it forms with the hemoglobin of the blood, and this is attended by disintegration of the red corpuscles. There is anaesthesia of the whole body, and death occurs through paralysis of the respiratory centre. Artificial respiration does not restore life. It is a convenient agent for the destruction of noxious insects, moths, bugs, etc. It has also been recommended for exterminating rats and mice. Frogs and cats are said to be less affected by carbon disulphide than are birds, rabbits, and guinea-pigs. In factories, where carbon disulphide is used daily for dissolving caoutchouc, etc., it acts as a chronic poison, producing peripheral neuritis, and disorders of the digestive tract. T. Bokorny studied the action of carbon disulphide on plants; B. Heinze, and K. Störmer, on soils; and P. Zöller, H. Schiff, and M. Ckandi-Bey, its action on bacteria.

The uses of carbon disulphide.—Carbon disulphide is employed in the vulcanization of rubber; in the extraction of essential oils; and as a solvent for oils, fats, and waxes; it is used in the preparation of carbon tetrachloride, ammonium thiocyanate, viscose or artificial silk, and many organic compounds; as an insecticide in the preservation of grain and foods; in the preparation of antidotes to phylloxera; as a parasiticide; as a local anæsthetic; etc. In industrial work, special precautions have to be taken against the inflammability and poisonous nature of the fumes.

§ 43. The Thiocarbonic Acids and the Thiocarbonates

The thiocarbonates were discovered by J. J. Berzelius¹ in 1826, and described in his paper: *Om svafnellsalter*. He noticed that carbon disulphide dissolves in a solution of sodium sulphide, and when alcohol is added, sodium thiocarbonate is precipitated as a yellowish-brown oil; further, if dil. hydrochloric acid is added to sodium thiocarbonate, the free thiocarbonic acid, which he called *Kohlenschwefelwasserstoffsäure*, separates as a yellowish-red oil. W. C. Zeise called the acid *Rothsäure*, or *Hydrothiocarbonsäure*. The thiocarbonates are analogous to the carbonates with sulphur in place of oxygen; and carbon disulphide, by this view, is thiocarbonic anhydride, CS₂, and thiocarbonic acid is constituted H₂CS₃. The thiocarbonates are salts of the type M₂'CS₃. They are in general unstable, although thiocarbonic acid itself is much more stable than carbonic acid; a fact possibly associated with the gaseous character of the carbonic anhydride, and the liquid character of thiocarbonic anhydride at ordinary temp. Just as ordinary carbonic acid, CO(OH)₂, is metacarbonic acid, derived from orthocarbonic acid, C(OH)₄, by the loss of a mol. of water, so can ordinary thiocarbonic acid be regarded as **metathiocarbonic acid**, CS(SH)₂, derived from **orthothiocarbonic acid**, C(SH)₄, by the loss of a mol. of hydrogen sulphide. The ortho-acid is not known, but P. Clässon prepared an oily liquid *ethyl orthothiocarbonate*, C(S'Al₂)₄, by the action of carbon tetrachloride on sodium ethyl sulphide, Na.S.C₂H₅. There are six possible sulphur derivatives of metathiocarbonic acid, and they can be designated in many ways. A. Hemminger applied the affix *sulpho-* when the oxygen atom of the carbonyl group is displaced by sulphur, and *thio-* when the oxygen atoms of the hydroxyl groups are displaced; or the affix *thiol-* or *thio-* can be used when sulphur displaces the oxygen of the hydroxyl groups, and *thion-* for a similar displacement in the carbonyl group. The sulphur atoms of the SH-groups can be designated α-, and the sulphur atom of the CS-group, β-; and the acids with one, two, and three sulphur atoms respectively called mono-, di-, and tri-thiocarbonic acids with α- or β- prefixed to represent the disposition of the sulphur atoms present. In the case of trithiocarbonic acid, of course no prefix is needed. Thus,

$\begin{array}{c} \text{HO} \diagup \text{CO} \\ \text{HO} \diagdown \end{array}$	$\begin{array}{c} \bullet \text{HO} \diagup \text{CS} \\ \text{HO} \diagdown \end{array}$	$\begin{array}{c} \text{HS} \diagup \text{CO} \\ \text{HO} \diagdown \end{array}$	$\begin{array}{c} \text{HS} \diagup \text{CS} \\ \text{HO} \diagdown \end{array}$	$\begin{array}{c} \text{HS} \diagup \text{CO} \\ \text{HS} \diagdown \end{array}$	$\begin{array}{c} \text{HS} \diagup \text{CS} \\ \text{HS} \diagdown \end{array}$
Carbonic acid.	• Sulphocarbonic acid, or orthothiocarbonic acid; β-thiocarbonic acid.	Thiocarbonic acid, or thiolcarbonic acid; α-thiocarbonic acid.	Sulphothiocarbonic acid; or thiolthiocarbonic acid; αβ-dithiocarbonic acid.	Dithiocarbonic acid; or dithiolcarbonic acid; αα-dithiocarbonic acid.	Dithiolthiocarbonic acid; or trithiocarbonic acid; usually thiothiocarbonic acid.

It will be observed that thioncarbonic and thiolcarbonic acids are isomeric monothiocarbonic acids; and thiolthioncarbonic and dithiolcarbonic acids are isomeric dithiocarbonic acids. W. C. Zeise found that carbon disulphide dissolves in an alcoholic soln. of potassium hydroxide, forming *potassium ethylxanthate*, C₂H₅O.CS.SK. This is the potassium salt of what W. C. Zeise called *rotverderendes Salz* or *Xanthogensäure*, and is now called **xanthic acid** or **xanthogenic acid**, C₂H₅O.CS.SH—*ξανθός*, yellow; *γεννάω*, I generate—in allusion to the colour of the copper salt. When the potassium salt is treated with dil. sulphuric acid at 0°, the free acid is produced as an oily liquid. When heated to 24°, the acid decomposes into ethyl alcohol and carbon disulphide, and hence, unless xanthic acid undergoes some peculiar intra-molecular change before decomposition it is inferred that it cannot be constituted: C₂H₅S.CS.OH, or C₂H₅S.CO.SH. Xanthic acid is therefore the ethyl derivative of thiolthioncarbonic acid. Xanthic acid usually decomposes violently a few minutes after it has been prepared owing to the catalytic action of the alcohol formed as a product of its decomposition. If intimately mixed with phosphoric oxide, the acid is far more stable and it can be kept for weeks. The rate of decomposition of the acid is greatly influenced by the solvent. Thus, the velocity constant for ethyl alcohol is 1,000,000, and for carbon disulphide, unity.

There is no relation between the dielectric constant of the solvent and the speed of the reaction. H. von Halban and co-workers have studied the kinetics of the decomposition. The influence of different solvents on the speed of a reaction is well illustrated by the following experiment due to H. von Halban and A. Kirsch :

A soln. of 0.8 gm. of potassium xanthate in water at 0° is treated with 40 c.c. xylene and the calculated amount of ice-cold dil. sulphuric acid. The mixture is shaken vigorously in a separating funnel and the xylene soln. is removed, dried with calcium chloride, followed by phosphoric oxide; filtered and diluted to 50 c.c. If one c.c. of this soln. with 10 c.c. of the given solvent is treated with 10 c.c. of a soln. of 0.29 gm. of hydrated cobalt nitrate in 100 c.c. of alcohol, a dark green soluble cobaltic xanthate is formed, and some xanthic acid remains undecomposed. With ethyl alcohol and acetone as solvents, decomposition is complete in a few minutes; with nitromethane, the xanthic acid is not quite all decomposed after half an hour's action, and with glacial acetic acid after an hour's action; boiling for half an hour with chloroform, ether, benzene, carbon disulphide does not decompose all the xanthic acid.

Other alcohols give products analogous to xanthic acid, thus, J. B. A. Dumas and E. Péligot, P. Desains, and H. S. Fry, made **methylxanthic acid**, $\text{CH}_3\text{O.CS.SH}$, by the action of magnesium on a soln. of carbon disulphide in methyl alcohol. *Potassium ethyl α -thiocarbonate*, $\text{C}_2\text{H}_5\text{O.CO.SH}$, prepared by H. Debus,² G. Chancel, and C. Bender is a derivative of thiocarbonic acid; *diethyl β -thiocarbonate*, $\text{C}_2\text{H}_5\text{O.CS.OCC}_2\text{H}_5$, prepared by R. Nasini, *ethyl chloro- β -thiocarbonate*, $\text{C}_2\text{H}_5\text{O.CS.Cl}$, prepared by P. Klason; and *xanthogenamide*, $\text{C}_2\text{H}_5\text{O.CS.NH}_2$, prepared by F. Salomon, H. Debus, and G. Chancel, are representatives of thioncarbonic acid; *potassium ethyl $\alpha\beta$ -dithiocarbonate*, or xanthic or xanthogenic acid, $\text{C}_2\text{H}_5\text{O.CS.SH}$, prepared as indicated above, is a derivative of thiolthioncarbonic acid; *diethyl $\alpha\alpha$ -dithiocarbonate*, $\text{C}_2\text{H}_5\text{S.CO.SC}_2\text{H}_5$, prepared by R. Schmitt and L. Glutz, F. Salomon, and R. Seiffert, is a representative of dithiocarbonic acid; and *monoethyl trithiocarbonate*, $\text{C}_2\text{H}_5\text{S.CS.SH}$, prepared by G. Chancel, and *diethyl trithiocarbonate*, $\text{C}_2\text{H}_5\text{S.CS.SC}_2\text{H}_5$, prepared by P. Klason, P. Schweitzer, H. Debus, A. Husemann, R. Nasini and A. Scala, and C. Löwig, are derivatives of trithiocarbonic acid.

As indicated above, *dithiolthioncarbonic acid*, or *trithiocarbonic acid*, or simply **thiocarbonic acid**, H_2CS_3 , was prepared by J. J. Berzelius³ by adding cold dil. hydrochloric acid to a soln. of a thiocarbonate. The acid separates as a dark yellow or reddish-brown oil. W. C. Zeise added that if too much acid is added in the preparation, the oil dissolves, and if the acid be too conc. hydrogen sulphide is evolved. J. G. O'Donoghue and Z. Kahan prepared it by slowly dropping a soln. of calcium thiocarbonate into conc. hydrochloric acid. Both soln. were previously cooled in a freezing mixture, and the vessel containing the mixture was allowed to stand for some time after all the calcium thiocarbonate soln. had been added. After an hour or two, the liquid was decanted, the last drops being separated with a separating funnel. The oil was sometimes washed rapidly with ice-cold water. It was then placed in a small flask surrounded by a freezing mixture, calcium chloride added, and the flask attached to a good pump until bubbles no longer appeared to arise from the oil. In this way hydrochloric acid and water were removed, and the oil was finally dried over phosphorus pentoxide. E. W. Yeoman found that if purified thiocarbonates are employed, and oxygen be excluded, no oil is produced at 0°; but if air has access, then an oily liquid slowly separates. Impure thiocarbonates, and purified perthiocarbonates give an oily liquid at ordinary temp. The red oil is therefore assumed to be **perthiocarbonic acid**, H_2CS_4 , and it separates from the soln. owing to its insolubility; it is further assumed that thiocarbonic acid, H_2CS_3 , is soluble in water. If this be correct, the following description refers to perthiocarbonic acid and not to thiocarbonic acid.

Thiocarbonic acid is an oily liquid with a disagreeable, pungent odour. J. G. O'Donoghue and Z. Kahan state that their analyses of the oil always showed an excess of sulphur beyond that required for H_2CS_3 , so that it was inferred that the acid always holds some sulphur in soln. The oil can be distilled at 50° with decom-

position. Abortive attempts were made to distil the acid under diminished press. from a flask connected with two receivers surrounded by liquid air. J. J. Berzelius stated that the oil decomposed into carbon disulphide and hydrogen sulphide. According to J. G. O'Donoghue and Z. Kahan, thiocarbonic acid is soluble in alcohol, giving a yellow soln. which decomposes rapidly with deposition of sulphur and formation of carbon disulphide and hydrogen sulphide. It is also soluble in liquid ammonia, turpentine, toluene, ether, or chloroform, in all of which solvents it very soon decomposes, but is most stable in the two latter. H. von Halban and co-workers measured the rate at which the thiocarbonates decompose when dissolved in different solvents; they also measured the absorption spectra of soln. of trithiocarbonic acid and of its ethyl salt in chloroform, alcohol, light petroleum, ether, and toluene; and of the barium salt in water. Marked differences were obtained in the spectra of the acids and the salts. The existence of the free acid in the soln. was indicated by the similarity between the spectrum of a soln. of the sodium salt and that for a soln. of the acid in an organic solvent. In liquid air or solid carbon dioxide, this carbonic acid forms a pink solid which melts again to a red liquid on removing the refrigerator. The acid is insoluble in water, but is at once decomposed by it, with evolution of hydrogen sulphide and formation of carbon disulphide and sulphur. This also occurs in a soln. of common salt. It is much more stable towards strong acids, especially hydrochloric acid, under which it can be kept for several days if cool. The colour, however, gradually fades, and finally only carbon disulphide is left. In air, it gradually evaporates, often leaving a brownish-black residue consisting largely of sulphur. Sometimes it has been kept for a few days in a loosely-stoppered flask without any considerable loss. The oil dissolves flowers of sulphur readily with a slight darkening in colour, and it is possible, therefore, that the colour of the oil is due to dissolved sulphur. It does not burn on water like carbon disulphide. Sodium and potassium act on the dry oil or on its ethereal soln. Potassium decomposes it very violently, giving an immediate yellow, crystalline precipitate of potassium thiocarbonate, whilst, in the former case, sodium thiocarbonate gradually separates. Hydrogen sulphide and probably hydrogen are evolved in both cases. Magnesium powder has apparently little action on the oil, and on trituration with mercury a red solid is obtained. It is soluble in an excess of hydrochloric or sulphuric acid, and reacts with the alkali carbonates liberating carbon dioxide, and forming thiocarbonates.

J. J. Berzelius and A. Marcet found that carbon disulphide slowly absorbs ammonia to form a slightly yellow amorphous powder which can be sublimed; it absorbs water with avidity, forming first an orange-yellow soln., presumably of ammonium thiocarbonate, and then a lemon-yellow liquid, which is converted into ammonia, sulphuric acid, and carbonic acid. W. C. Zeise made ammonium thiocarbonate, $(\text{NH}_4)_2\text{CS}_3$, by mixing a sat. alcoholic soln. of ammonia with one-tenth of its vol. of carbon disulphide; cooling the mixture after it has become brown, pouring off the mother-liquor, washing the crystals several times with alcohol, then with ether, and finally drying the crystals by press. between filter paper. E. Mulder said that if the right proportions are used, the thiocarbonate alone crystallizes out. The mother-liquor was found by W. C. Zeise to contain much ammonium thiocarbonate and sulphide; and H. Debus said that when alcoholic ammonia and carbon disulphide react, ammonium thiocyanate and thiocarbamate are formed as well as ammonium thiocarbonate. Indeed, said J. G. O'Donoghue and Z. Kahan, the pale yellow, crystalline precipitate obtained by shaking dried carbon disulphide with a sat. soln. of ammonia in alcohol, behaves quite differently from ammonium thiocarbonate. E. W. Yeoman saturated with hydrogen sulphide a 20 per cent. soln. of dry ammonia in alcohol, and after warming to $35^\circ\text{--}40^\circ$ and simultaneously passing in hydrogen to exclude air, added a slight excess of carbon disulphide, and dry ether until a permanent turbidity was produced. On cooling the soln. slowly, red crystals separated. These were collected in hydrogen, washed with dry ether, and dried in a current of hydrogen at ordinary temp. A. Gélis

made ammonium thiocarbonate by the action of carbon disulphide on ammonium sulphide. J. G. O'Donoghue and Z. Kahan made it by the action of liquid ammonia, on an alcoholic soln. of thiocarbonic acid; the yellowish pink soln., on evaporation, gave a yellow solid which soon decomposed: $(\text{NH}_4)_2\text{CS}_3 = (\text{NH}_4)_2\text{S} + \text{CS}_2$; and $(\text{NH}_4)_2\text{S} = 2\text{NH}_3 + \text{H}_2\text{S}$. J. Volhard, and C. Delitsch made ammonium thiocarbonate by heating ammonium thiocyanate to 170° for 100–120 hrs., or to 180° – 190° for 20 hrs.

Ammonium thiocarbonate, said W. C. Zeise, forms pale yellow crystals, which, when exposed to air, volatilize completely in a few days. If protected from moisture, the salt may be sublimed almost unchanged, but a small quantity of ammonium sulphide appears to be formed during the process. E. W. Yeoman found that the salt dissociates completely at 100° , and leaves no residue. The salt dissolves rapidly and copiously in water; a soln. with one part of the salt in eight parts of water is red; with a greater proportion of water, the soln. is brown; and with a still greater proportion of water, yellow; if the aq. soln. be kept in a closed vessel, it turns reddish-brown; the soln. is decolorized on exposure to air, and a grey carbonaceous precipitate settles. E. W. Yeoman said that aq. soln. of the salt are very unstable, easily losing carbon disulphide, hydrogen sulphide, and ammonia, and some oxidation occurs. This change occurs rapidly when the aq. soln. is boiled in an open vessel, very little thiocyanate or carbamide being formed. J. H. Gladstone gave 1.065 for the sp. gr. of a soln. of an eq. of the salt with 35.47 eq. of water, and for the refractive indices 1.3918 with the *A*-line, and the *D*-line. A. Gélis said that the soln. decomposes at 90° – 100° , forming ammonium thiocyanate and hydrogen sulphide. According to W. C. Zeise, when the salt is moistened with alcohol, and exposed to the air, it immediately assumes a deeper yellow tint, and in a few seconds it becomes red; if the salt has been very well washed with ether and pressed thoroughly dry, it will retain its colour for 5 min. in air, and in closed vessels for a longer time. The salt dissolves sparingly in alcohol, and is still less soluble in ether. When left with alcohol in a closed vessel, the salt decomposes: $(\text{NH}_4)_2\text{CS}_3 = (\text{NH}_4)_2\text{CS}_2(\text{NH}_2) + \text{H}_2\text{S}$. When mixed with an aq. soln. of potassium hydroxide and evaporated, the residue is potassium thiocyanate; with lime-water, it furnishes a yellow powder, and the soln. still contains thiocarbonates. E. W. Yeoman found that the aq. soln. dissolves a gram-atom of sulphur per mol. of salt. Hydrochloric and sulphuric acids decolorize the red aq. soln. and render it turbid owing to the separation of thiocarbonic acid, and, with an excess of more conc. acids, the precipitate is dissolved. When a conc. aq. soln. is treated with conc. acids, hydrogen sulphide is given off; but with moderately dil. sulphuric acid, thiocarbonic acid is formed without the evolution of hydrogen sulphide. H. Hager, J. A. Palmer, and H. Siepmann have discussed the use of ammonium thiocarbonate in place of ammonium sulphide in analytical chemistry. O. Loew treated a soln. of thiocarbonic acid in ammonium sulphide, with hydrochloric acid, and digested the precipitate with aq. ammonia. The red soln. was supposed to contain ammonium sesquithiocarbonate, $(\text{NH}_4)_2\text{C}_2\text{S}_3$, and decomposed on evaporation or on standing (see p. 134).

J. J. Berzelius, and C. W. Zeise prepared potassium thiocarbonate, K_2CS_3 , by dissolving carbon disulphide in a soln. of potassium monosulphide, or hydroxide—in the latter case some carbonate, as well as thiocarbonate, is formed: $3\text{CS}_2 + 6\text{KOH} = \text{K}_2\text{CO}_3 + 2\text{K}_2\text{CS}_3 + 3\text{H}_2\text{O}$. He recommended adding carbon disulphide to an alcoholic soln. of potassium sulphide so long as it dissolves; the lowest stratum which separates on standing is separated from the two upper ones—the middle stratum is mainly carbon disulphide, and the top one mainly alcohol—and evaporated at 30° for crystallization; or saturating at 30° an aq. soln. of potassium sulphide with carbon disulphide in a closed vessel quite full of the mixture, and evaporating as before at 30° . H. Hager made the salt by digesting potassium hydroxide with a soln. of sulphur in carbon disulphide; and B. Holmberg, and E. Bijlmann treated an alcoholic soln. of potassium hydrosulphide with carbon disulphide. E. W. Yeoman dissolved 2 grms. of potassium in absolute alcohol, converted the soln. into hydro-

sulphide, at 45°–50°, and then added carbon disulphide. As the soln. cooled yellow crystals were formed. These were washed with dry ether, and dried in a current of dry hydrogen at 45°. J. G. O'Donoghue and Z. Kahan precipitated the salt by adding an alcoholic soln. of potassium hydroxide to thiocarbonic acid. The salt was purified by evaporating the soln. in liquid ammonia. According to J. J. Berzelius, the yellow crystalline salt is very deliquescent; and it loses water of crystallization between 60° and 80°. When heated out of contact with air, it forms potassium sulphide and carbon. It is readily soluble in water, and sparingly soluble in alcohol. According to N. Tarugi and A. Magri, when an aq. soln. of potassium thiocarbonate is boiled out of contact with air and in an atm. of nitrogen, the first phase of the decomposition occurring is represented by the equation $K_2CS_3 = K_2S + CS_2$. The potassium sulphide thus formed subsequently undergoes hydrolysis, giving potassium hydroxide and hydrogen sulphide: $K_2S + 2H_2O = 2KOH + H_2S$. In presence of air or oxygen, the decomposition of the thiocarbonate effected by boiling its soln. is represented by the equation: $2K_2CS_3 + 2H_2O + 2O_2 = K_2S_2O_3 + K_2CO_3 + CS_2 + 2H_2S$. Finally, in an atm. of carbon dioxide, decomposition occurs according to the equation: $K_2CS_3 + CO_2 + H_2O = K_2CO_3 + CS_2 + H_2S$. J. J. Berzelius' equation: $K_2CS_3 + 3H_2O = K_2CO_3 + 3H_2S$, does not represent the reaction. Under the action of sunlight and in presence of air, soln. of thiocarbonates undergo, at the ordinary temp. and with an increased velocity, the same transformation as takes place on boiling in absence of sunlight. In vessels evacuated and then exposed to sunlight, thiocarbonates remain unaltered for a long time, the equilibrium $K_2CS_3 = K_2S + CS_2$ not being disturbed by the removal of one of the products of the decomposition. Towards organic compounds, thiocarbonates behave in such a way as to confirm the fact that they decompose into a sulphide and carbon disulphide. Thus, with aniline, potassium thiocarbonate yields the condensation product of thioformanilide. Under other conditions, thiocarbonates behave like simple sulphides; thus benzoyl chloride and a thiocarbonate in equimol. proportions yield benzoyl disulphide, which is also formed by the interaction of benzoyl chloride and potassium hydrogen sulphide. According to J. G. O'Donoghue and Z. Kahan, it is readily soluble in liquid ammonia. E. W. Yeoman found a soln. containing a mol of the salt in water dissolves a gram-atom of sulphur.

H. Hager and T. Rosenblatt discussed the use of the salt in place of ammonium sulphide in analytical work. The detection and determination of thiocarbonates have been discussed by A. and T. Gélis, C. Vincent, E. L. de Bouquet, E. Fallières, G. Danneccy, O. Hehner and H. S. Carpenter, etc. The thiocarbonate is converted into the lead or zinc salt, and decomposed by acetic acid (B. Delachanal and A. Mermet), by arsenious acid (M. David and A. Rommier), or by heat (L. Finot and A. Bertrand). The resulting carbon disulphide is received in olive oil, or alcoholic potash (B. Delachanal and A. Mermet), or measured in a graduated cylinder (M. David and A. Rommier), or estimated by the loss of weight (L. Finot and A. Bertrand), or the alcoholic potash and xanthate is titrated with iodine (B. Delachanal and A. Mermet). P. Thénard, J. Maistre, M. de Georges, A. Mares, F. Sestini, and A. Mermet have discussed the use of thiocarbonates for the destruction of the *phyloxera vestatrix*, and other cryptogamous diseases of plants.

According to J. J. Berzelius, lithium thiocarbonate, Li_2CS_3 , is obtained by a process similar to that which he employed for the potassium salt. The salt is more deliquescent than the sodium or potassium salt; and it is readily soluble in both water and alcohol. J. J. Berzelius made sodium thiocarbonate, Na_2CS_3 , by digesting an aq. soln. of sodium monosulphide with carbon disulphide in a closed vessel at 30°, and evaporating the liquid. A. Husemann half sat. sodium hydroxide with hydrogen sulphide, and mixed the product with carbon disulphide. He then added alcohol or a mixture of ether and alcohol and obtained sodium thiocarbonate as a red oil which was freed from carbon disulphide by heat. I. Taylor made the salt by the action of sodium amalgam—preferably in the presence of a strip of platinum—on water in the presence of carbon disulphide—carbon dioxide and hydrogen

are evolved. J. G. O'Donoghue and Z. Kahan found that when dry, freshly-prepared sodium ethoxide is added to thiocarbonic acid, a yellow crystalline precipitate is gradually formed which can be washed with cold alcohol. E. W. Yeoman made it by a process analogous to that used for the potassium salt. According to J. J. Berzelius, the yellow salt can be crystallized from its aq. soln. The yellow needle-like crystals of the salt are very deliquescent, and readily soluble in water and alcohol. It is insoluble in ether or benzene, both of which precipitate the salt from its alcoholic soln. According to E. W. Yeoman, sodium thiocarbonate is stable in dry air free from carbon dioxide. If moisture be present, the salt decomposes with the loss of carbon disulphide, and is oxidized: $\text{Na}_2\text{CS}_3 = \text{Na}_2\text{S} + \text{CS}_2$; $\text{Na}_2\text{S} + \text{H}_2\text{O} = \text{NaHS} + \text{NaOH}$; $2\text{NaHS} + \text{O} = \text{Na}_2\text{S}_2 + \text{H}_2\text{O}$; and $\text{Na}_2\text{S}_2 + 3\text{O} = \text{Na}_2\text{S}_2\text{O}_3$. The salt decomposes, when strongly heated, into sodium disulphide and carbon disulphide. According to J. J. Berzelius, when dried and heated to redness in closed vessels, it decomposes into a mixture of carbon and sodium sulphide. E. W. Yeoman found that if water be excluded, the salt is stable in a current of hydrogen at 60° ; but at 75° , carbon disulphide escapes, but the loss is not great even at 100° . A current of dry air free from carbon dioxide does not cause any more decomposition than occurs with hydrogen. An aq. soln. is stable in the absence of oxygen and carbon dioxide, but in the presence of oxygen, carbon disulphide separates, and thiosulphates, polysulphides, and sulphur are formed, while the unchanged thiocarbonate dissolves sulphur, forming perthiocarbonate, which also decomposes by the loss of carbon disulphide and the subsequent oxidation of the alkali sulphide. J. J. Berzelius represented the reaction with water: $\text{Na}_2\text{CS}_3 + 3\text{H}_2\text{O} = \text{Na}_2\text{CO}_3 + 3\text{H}_2\text{S}$, which E. W. Yeoman found to be true when an air-free soln. is heated in a sealed tube at 100° , the reactions being $\text{Na}_2\text{CS}_3 = \text{Na}_2\text{S} + \text{CS}_2$; $\text{Na}_2\text{S} + 2\text{H}_2\text{O} = 2\text{NaOH} + \text{H}_2\text{S}$; and $6\text{NaOH} + 3\text{CS}_2 = \text{Na}_2\text{CO}_3 + 2\text{Na}_2\text{CS}_3 + 3\text{H}_2\text{O}$. The re-formed thiocarbonate again decomposes, and after prolonged heating, the reaction reduces to that given by J. J. Berzelius. The reaction is never quite complete. If air be present, thiosulphate and polysulphide are formed. When sodium thiocarbonate is distilled with air-free water, in the absence of air and carbon dioxide, hydrogen sulphide and carbon disulphide are formed; the residue contains sodium sulphide and its hydrolytic products, but no carbonate and only a trace of thiosulphate due to leakage of air. This agrees with N. Tarugi and A. Magri's observations. If a stream of air be drawn through a boiling soln., E. W. Yeoman obtained results in partial agreement with those of N. Tarugi and A. Magri, who represented the reaction: $2\text{Na}_2\text{CS}_3 + 2\text{H}_2\text{O} + 2\text{O}_2 = \text{Na}_2\text{S}_2\text{O}_3 + \text{CS}_2 + \text{Na}_2\text{CO}_3 + 2\text{H}_2\text{S}$. The salt and its aq. soln. are decomposed by carbon dioxide, forming carbonate and carbon disulphide; sulphur dioxide forms sulphite and carbon disulphide. A soln. of a mol. of the salt in water dissolves a gram-atom of sulphur, as observed by A. Gélis. In alcoholic soln., it was found that $\text{Na}_2\text{S} + \text{CS}_2 = \text{Na}_2\text{CS}_3 + 5.7 \text{ Cals.}$; and $\text{Na}_2\text{S}_2 + \text{CS}_2 = \text{Na}_2\text{CS}_4 + 8.55 \text{ Cals.}$; $\text{Na}_2\text{CS}_3 + \text{S} = \text{Na}_2\text{CS}_4 + 4.29 \text{ Cals.}$

M. Cluzel stated that when carbon disulphide is passed over red-hot copper, carbon is separated and deposited on the surface of the metal, but J. J. Berzelius, and L. J. Thénard and L. N. Vauquelin said that the carbon disulphide combines as a whole with the metal, forming a shining black substance which, when treated with nitric acid, leaves a residue of carbon. • A. Cavazzi observed the formation of no compound of carbon and sulphur with copper under these conditions—*vide supra*, action of carbon disulphide on copper. J. J. Berzelius found that cupric salts give a dark brown precipitate when added to a soln. of calcium thiocarbonate; the precipitate was considered to be **cupric thiocarbonate**; it is soluble in an excess of calcium sulphide; and when heated, it gives off carbon disulphide, and sulphur, and cuprous sulphide remains. M. Ragg said that when a soln. of a cupric salt is treated with an alkali xanthate, not only is cupric thiocarbonate, CuCS_3 , but also **cupric oxydthiocarbonate**, CuCOS_2 , and **cupric dioxythiocarbonate**, CuCO_2S , are formed. K. A. Hofmann and F. Hochtlen obtained a complex of **cuprous thiocarbonate**, Cu_2CS_3 , and potassium cyanide, namely, **potassium cuprous dicyanothio-**

carbonate, $\text{Cu}_2\text{CS}_3 \cdot 2\text{KCy} \cdot 2\text{H}_2\text{O}$, by the action of ammonium cuprous thiocarbonate on a soln. of potassium thiocarbonate. According to K. A. Hofmann, and C. A. Hofmann and F. Höchtlen, **ammonium cuprous thiocarbonate**, NH_4CuCS_3 , is obtained by treating a mixture of cuprous chloride, dissolved in conc. hydrochloric acid and excess of ammonia (10 per cent.), with carbon disulphide at 0° ; after remaining three days, a separation of hair-like crystals takes place, and after another two days these are converted into the new salt. This crystallizes in thick, green tablets having a metallic lustre, and is only very sparingly soluble in conc. ammonia, and gives a brown soln. and a precipitate of brownish-black flocks with dil. sodium hydroxide. It is also obtained by the action of ammonia and carbon disulphide on copper sulphate at 10° . K. A. Hofmann and F. Höchtlen also prepared **potassium cuprous thiocarbonate**, KCuCS_3 , by adding a conc. soln. of cupric chloride to carbon disulphide dissolved in aq. potassium hydroxide at 0° ; it crystallizes in thick plates having a greenish lustre. Both salts are converted by acetic acid or, better, by sodium hydrogen sulphite, into **cuprosulphotri-thiocarbonate**, $\text{Cu}_2\text{S} \cdot 2\text{CuCS}_3$, or $\text{C}_2\text{S}_2 \cdot \text{Cu}_4$, which forms six-sided plates with a bronze-like lustre and is insoluble in water.

K. A. Hofmann also reported a **copper aminooxythiocarbonate**, $\text{Cu}_3\text{C}_2\text{S}_3(\text{NH}_2)_2\text{O}_8$, to be obtained by allowing a mixture of copper sulphate, 6 per cent. ammonia, and carbon disulphide to remain at 0° for 4-5 weeks. It crystallizes in black, monoclinic tablets, dissolves easily in ammonia with a blue coloration, is insoluble in water, and is not decomposed when allowed to remain over sulphuric acid. Dil. sodium hydroxide has only a surface action on the compound; but it is completely decomposed by conc. sodium hydroxide with the formation of cupric hydroxide, etc.

According to J. J. Berzelius, aq. soln. of calcium thiocarbonate and silver nitrate furnish a dark brown precipitate, presumably **silver thiocarbonate**. It dissolves in an excess of the calcium salt, giving a dark brown soln. The dried precipitate is black, shining, and difficult to pulverize; and when heated in a closed vessel, gives off sulphur, a little carbon disulphide, and leaves a mixture of silver sulphide and carbon. W. C. Zeise also made analogous observations with silver salts and the alkali thiocarbonates. J. J. Berzelius found that an aq. soln. of auric chloride and calcium thiocarbonate gives a turbid mixture which becomes clear, depositing a greyish brown precipitate—possibly **gold thiocarbonate**. This, when heated, gives off sulphur and leaves gold blackened by charcoal.

J. J. Berzelius digested calcium sulphide, water, and an excess of carbon disulphide in a closed vessel at 30° , and obtained a dark red liquid, which, when evaporated in vacuo, gave a yellowish-brown crystalline mass, this, when thoroughly dried, was citron-yellow. It was regarded as normal **calcium thiocarbonate**, CaCS_3 . On exposure to air, water is absorbed, and the colour becomes brownish-red. The product is readily dissolved by alcohol and water, but in the latter case, a basic salt remains as a residue. The aq. soln. is decomposed by boiling, and calcium carbonate is deposited. It is, however, doubtful if the normal thiocarbonate has been made; all E. W. Yeoman's attempts gave complexes of the normal salt with calcium hydroxide. Quite a number of these basic salts has been reported, but there is little to show which are chemical individuals. F. Sestini reported the formation of orange-red, prismatic crystals of **calcium hexahydroxythiocarbonate**, $3\text{Ca}(\text{OH})_2 \cdot \text{CaCS}_3 \cdot 7\text{H}_2\text{O}$, by exposing a mixture of water, calcium hydroxide, and carbon disulphide to the action of solar light in summer; in 6-8 hrs. the liquid acquires a yellowish-red colour, and then deposits the crystals. The same compound is made by heating milk of lime with carbon disulphide for 2 hrs. at 50° ; and adding a soln. of calcium hydroxide to the cooled filtrate. F. Sestini utilized the reaction for the detection of carbon disulphide in soln. D. Walker obtained bright orange-red needles of **calcium tetrahydroxythiocarbonate**, $2\text{Ca}(\text{OH})_2 \cdot \text{CaCS}_3 \cdot 6\text{H}_2\text{O}$, by agitating milk of lime with carbon disulphide. The salt is sparingly soluble in cold water, and is decomposed by boiling water; it is insoluble in carbon disulphide, and in alcohol. E. W. Yeoman obtained reddish-yellow needles of a similar salt, $3\text{Ca}(\text{OH})_2 \cdot \text{CaCS}_3 \cdot 9\text{H}_2\text{O}$, from aq. soln., and similar needles, but with the composi-

tion **dihydrated calcium dihydroxythiocarbonate**, $\text{Ca}(\text{OH})_2 \cdot \text{CaCS}_3 \cdot 2\text{H}_2\text{O}$, from alcoholic soln. S. Dyson discussed the occurrence of thiocarbonates in gas liquor from gas-works. The foul-line of gas-works is lime which has been used for removing hydrogen sulphide from coal gas; this when moist, and mixed with an equal weight of slaked lime, is an absorbent for carbon disulphide in gases. The absorption stops at a stage when about one-third of the sulphide has been converted into thiocarbonate, on the assumption that the reaction is $\text{CaS} + \text{CS}_2 = \text{CaCS}_3$. V. H. Veley has studied the reactions. He showed that dry calcium sulphide does not absorb the vap. of carbon disulphide, but the moist sulphide does absorb the vap.; nor does the absorption occur with calcium hydrosulphide. Calcium sulphide, nearly anhydrous, was placed under a small quantity of water, and hydrogen, sat. with carbon disulphide vap., passed into the mixture; the superincumbent water turned gradually to a red tint, and the soln. was separated from the sulphide by the method indicated above. The liquid was then placed under the air-pump; after a few days, red, prismatic needles appeared, from which the adherent water was drained as far as possible, and they were again dried under the air-pump. Analyses corresponded with **heptahydrated calcium tetrahydroxythiocarbonate**, $2\text{Ca}(\text{OH})_2 \cdot \text{CaCS}_3 \cdot 7\text{H}_2\text{O}$. The red prismatic crystals were very deliquescent, and on contact with air, lost their red colour, and became yellow and less soluble in water. An aq. soln. gave a red oil, thiocarbonic acid, when treated with hydrochloric acid. Further, when hydrogen, charged with the vap. of carbon disulphide, is passed into a soln. of calcium hydrosulphide, $\text{Ca}(\text{SH})_2$, white crystals of calcium hydroxyhydrosulphide, $\text{Ca}(\text{OH})(\text{SH})$, are formed, and there is a copious evolution of hydrogen sulphide; on continuing the passage of the gas, the crystals become yellow, and the liquid becomes nearly solid owing to the formation of a yellow crystalline mass. The crystals were drained from the mother-liquor, washed twice with distilled water, and dried in vacuo. The analysis of the yellow crystals corresponded with **decahydrated calcium tetrahydroxythiocarbonate**, $2\text{Ca}(\text{OH})_2 \cdot \text{CaCS}_3 \cdot 10\text{H}_2\text{O}$. This salt dissolves in water, forming a red soln. which, on evaporation, yields red crystals resembling the heptahydrate. There is a slight decomposition during the evaporation. Hence, V. H. Veley inferred that in removing carbon disulphide from coal gas, calcium sulphide or hydrosulphide is first converted into the hydroxyhydrosulphide; and this compound suspended in water is the active absorbent—hydrogen sulphide and a basic calcium thiocarbonate being simultaneously formed: $3\text{Ca}(\text{SH})(\text{OH}) + \text{CS}_2 + \text{H}_2\text{O} = 2\text{H}_2\text{S} + 2\text{Ca}(\text{OH})_2 \cdot \text{CaCS}_3$. Calcium thiocarbonate exposed to air is slowly converted into the carbonate, a change which is immediately effected by heating to $60^\circ\text{--}80^\circ$; in conc. soln., carbon disulphide is evolved, and calcium sulphide remains. The product is again effective as an absorbent for carbon disulphide. Basic calcium thiocarbonate is decomposed by hydrogen sulphide.

J. J. Berzelius reported the formation of a brownish-red liquid by the action of carbon disulphide on strontium sulphide and water in a closed vessel at 30° . On evaporation in vacuo, a lemon-yellow mass of **strontium thiocarbonate**, possibly SrCS_3 , is formed. E. W. Yeoman obtained the tetrahydrate, $\text{SrCS}_3 \cdot 4\text{H}_2\text{O}$, by suspending 10 grms. of strontium hydroxide in 60 c.c. of 95 per cent. alcohol, and converting it into the hydrosulphide by means of hydrogen sulphide at 70° with the exclusion of air. The carbonate was removed by filtration in hydrogen. A slight excess of carbon disulphide was added to the soln., and the mixture was kept for half an hour at 40° . Dark red needles were obtained on adding ether to the soln., and when dried in vacuo, the crystals were yellow. The mass becomes reddish-brown when moistened with water; and it is more soluble in water than the barium salt. F. Sestini obtained a non-crystalline mass of what he considered to be **strontium hexahydroxythiocarbonate**, resembling the corresponding calcium salt.

G. Chancel and F. Parmentier showed that baryta-water and carbon disulphide have very little action on one another in the cold, but at higher temp., a yellow liquid is formed, and barium carbonate precipitated. In a sealed tube at 100° , the reaction $\text{CS}_2 + 2\text{Ba}(\text{OH})_2 = \text{BaCO}_3 + \text{Ba}(\text{SH})_2 + \text{H}_2\text{O}$ is quantitative. J. J. Berzelius

found that hydrated barium sulphide rapidly unites with carbon disulphide, forming lemon-yellow, non-crystalline **barium thiocarbonate**, possibly BaCS_3 , which dissolves sparingly in water, forming a brownish-yellow soln., which, with more water, becomes red. On evaporation of the aq. soln. in vacuo, yellow crystals are obtained; and these, when moistened with water, become red, but on drying the yellow colour is restored. V. H. Veley added that the salt is readily soluble in hot water and is, at the same time, decomposed. He did not succeed in preparing the salt in a fit state for analysis, using water, alcohol—dil. and absolute—ether, and carbon disulphide as solvents. E. W. Yeoman made the barium salt by a process analogous to that used for strontium thiocarbonate. Unlike V. H. Veley, E. W. Yeoman found the barium salt even more stable than the other thiocarbonates. The chemical reactions resemble those of the sodium salt.

V. H. Veley found that carbon disulphide was not absorbed by solid barium hydroxide, or anhydrous barium sulphide; nor by a soln. of the hydrosulphide, or the crystalline hydroxyhydrosulphide mixed with a large excess of water—in which case, the hydroxyhydrosulphide is probably decomposed into the hydroxide and hydrosulphide. Carbon disulphide is copiously absorbed by the crystalline hydroxyhydrosulphide and a basic salt, possibly resembling the corresponding calcium salt, is obtained. D. Walker also made a **barium tetrahydroxythiocarbonate**, $2\text{Ba}(\text{OH})_2 \cdot \text{CaCS}_3 \cdot 6\text{H}_2\text{O}$, analogous to the calcium salt, and by a similar process. P. Thénard obtained the salt by shaking an aq. soln. of barium sulphide with carbon disulphide, washing the product with alcohol, and drying in vacuo. He said that 100 parts of water dissolve 1·5 parts of the salt. O. Loew claimed to have made **barium sesquithiocarbonate**, BaC_2S_3 , by warming sesquithiocarbonic acid, $\text{H}_2\text{C}_2\text{S}_3$, with barium hydrosulphide, and passing carbon dioxide through the filtrate so long as hydrogen sulphide is evolved. On evaporation, a non-crystalline mass is obtained which decomposes on exposure to air.

According to J. J. Berzelius, when magnesium sulphate is added to a soln. of barium thiocarbonate, and the filtrate evaporated in vacuo, a little carbon disulphide escapes, and the non-crystalline lemon-yellow residue is considered to be **magnesium thiocarbonate**. E. W. Yeoman also made this salt. Cold water in contact with this compound dissolves a part, forming a yellow soln., and leaving undissolved a basic salt, which is decomposed by boiling water leaving magnesium carbonate undissolved. F. Sestini claimed to have made a non-crystalline basic salt analogous to that which he obtained with calcium salts; D. Walker likewise claimed to have made a basic salt by a process analogous to that which he used for the calcium salt. According to I. Taylor, when a strip of magnesium, in contact with platinum as a catalyst, is immersed in a mixture of water and carbon disulphide, the liquid, in the course of a couple of days, acquires a yellow colour owing to the formation of magnesium thiocarbonate: $3\text{CS}_2 + 2\text{Mg} + \text{H}_2\text{O} = 2\text{MgCS}_3 + \text{CO} + \text{H}_2$. J. J. Berzelius found that when soln. of a zinc salt and calcium thiocarbonate are mixed, a yellowish-white precipitate is formed which, on drying, becomes reddish-yellow and translucent—it was supposed to be **zinc thiocarbonate**. According to A. Cavazzi, zinc and carbon disulphide vap. at a high temp. furnish zinc sulphide. D. Walker said that zinc hydroxide is not affected by agitation with carbon disulphide. J. G. O'Donoghue and Z. Kahan made zinc thiocarbonate, ZnCS_3 , as a pale yellow crystalline powder by the action of thiocarbonic acid alone, or in alcoholic or ethereal solg., on a zinc salt with a weak acid, at the temp. of solid carbon dioxide. The thiocarbonate is very unstable, and rapidly decomposes, forming zinc sulphide. K. A. Hofmann treated a zinc salt with carbon disulphide, and a 10 per cent. soln. of ammonia, and obtained a salmon-yellow crystalline powder of **zinc diamminothiocarbonate**, $\text{ZnCS}_3 \cdot 2\text{NH}_3$. J. J. Berzelius obtained a lemon-yellow precipitate, supposed to have been **cadmium thiocarbonate**, by a process similar to that employed for the zinc salt. J. G. O'Donoghue and Z. Kahan obtained the thiocarbonate, CdCS_3 , by a process like that they employed for the zinc salt. The deep yellow precipitate soon changed to a reddish-yellow colour, and then to reddish-brown cadmium sulphide.

K. A. Hofmann obtained **cadmium diamminothiocarbonate**, $\text{CdCS}_3 \cdot 2\text{NH}_3$, in lustrous plates, by the same process as that employed for the corresponding zinc salt; it decomposed when dried, forming cadmium sulphide. J. J. Berzelius found that mercuric salts react with soln. of calcium thiocarbonate, yielding a black precipitate, which dissolved in an excess of the thiocarbonate, and in drying gave off carbon disulphide, and left behind black mercuric sulphide. W. C. Zeise obtained a yellow precipitate—possibly **mercuric thiocarbonate**—by mixing soln. of ammonium thiocarbonate and a mercuric salt. The precipitate changes in the course of a few hours, with the separation of some carbon disulphide.

According to J. J. Berzelius, an aq. soln. of calcium thiocarbonate gives a dark brown precipitate with stannous salts—possibly **stannous thiocarbonate**—and a brownish-yellow precipitate with stannic salts—possibly **stannic thiocarbonate**. J. J. Berzelius also found that lead salts give a dark brown precipitate with calcium thiocarbonate, and W. C. Zeise, a red precipitate with ammonium thiocarbonate. The precipitate was considered to be **lead thiocarbonate**, PbCS_3 . J. G. O'Donoghue and Z. Kahan made it by the process they employed for the zinc salt. It appeared as a red salt with the composition PbCS_3 , and when pure, the salt darkened only slowly in air—usually the salt turns black in about half an hour. This change corresponds with $\text{PbCS}_3 \cdot \text{CS}_2 + \text{PbS}$, and occurs rapidly in vacuo, and is quantitative when the salt is heated in a current of hydrogen. J. J. Berzelius found that the salt under water decomposes in a few hours, but under alcohol, the decomposition is slower. The salt is instantly blackened by the action of a soln. of ammonium sulphide or of potassium hydroxide; at ordinary temp., sulphuric acid, nitric acid, or iodine has no appreciable effect on lead thiocarbonate. The salt was further examined by B. Delachanal and A. Mernet. A Gautier and L. Hallopeau also obtained crystals of undetermined composition by the action of the vapour of carbon disulphide on white-hot lead. J. J. Berzelius found that calcium thiocarbonate added to a soln. of a bismuth salt, gives a dark brown precipitate—possibly **bismuth thiocarbonate**—soluble in an excess of the precipitant, forming a reddish-brown soln.; he also obtained with chromic salts a greyish-green precipitate—possibly **chromium thiocarbonate**—which when heated in a closed vessel gave carbon disulphide and brown chromium sesquisulphide; with manganous salts, a dark brown liquid which turns yellow and then deposits a reddish-brown powder—possibly **manganese thiocarbonate**—which is sparingly soluble in water, forming a yellow soln., and decomposes when heated, forming carbon dioxide, sulphur, and manganese sulphide; with ferrous salts, a deep wine-red liquid is formed which becomes darker and ultimately appears ink-black by reflected light—if the ferrous salt be in excess, a black powder is deposited—possibly **ferrous thiocarbonate**; with ferric salts, a deep red precipitate is formed which retains its colour when dried, and is possibly **ferric thiocarbonate**, for, when heated, it gives off carbon disulphide and sulphur, and leaves a residue of iron sulphide; with cobalt salts, a deep olive-green soln. is formed which appears black by reflected light, and in 24 hrs. deposits black flakes—**cobalt thiocarbonate**—leaving the mother-liquor dark brown; and with nickel salts, a dark brownish-red soln. is obtained which, in 24 hrs., deposits black flakes—**nickel thiocarbonate**—and becomes brownish-yellow. C. D. Braun, and A. Mernet noted that aq. soln. of the alkali thiocarbonates give an intense red coloration with ammoniacal soln. of nickel salts. O. F. Wiede and K. A. Hofmann made **nickel triammino-thiocarbonate**, $\text{NiCS}_3 \cdot 3\text{NH}_3$, by gently warming a mixture of nickelous hydroxide, ammonia, and carbon disulphide. It crystallizes in transparent, ruby-red needles, is sparingly soluble in water, but easily in sodium hydroxide with an intense, yellowish-red coloration, and, when heated, gives off carbon disulphide. On exposure to the air, it gives off part of the ammonia and carbon disulphide. They also made **cobalt hexammino-thiocarbonate**, $\text{Co}_2\text{CS}_3 \cdot 6\text{NH}_3$, by passing nitric oxide through a mixture of freshly prepared cobaltous hydroxide, aq. ammonia, and carbon disulphide. The salt, which is mixed with an amorphous by-product, is purified by washing with alcohol. It crystallizes in black, lustrous

rhombohedra, dissolves sparingly in water, yielding a yellowish-green soln. and dissolves in sodium hydroxide with a dark green coloration, at first without evolution of ammonia. It is decomposed by strong acids with precipitation of sulphur, and, when heated, gives off carbon disulphide. By prolonged heating with sodium hydroxide, all the nitrogen is given off as ammonia. It can also be prepared by warming a mixture of cobalt hydroxide, ammonia, and carbon disulphide. H. A. Hofmann and co-workers made an analogous iron hexamino-thiocarbonate, $\text{Fe}_2(\text{C}_2\text{S}_7 \cdot 6\text{NH}_3 \cdot 2\text{H}_2\text{O})$.

K. A. Hofmann obtained the complex $\text{Co}_2\text{C}_2\text{S}_8(\text{NH}_3)_6\text{O}_3$ and cobalt pentamminosulphite by allowing the above hexammino-thiocarbonate to remain some months in contact with 10 per cent. aq. ammonia. The pentammine crystallizes in thin plates which can be removed by washing the mixture with conc. ammonia. The complex $\text{Co}_2\text{C}_2\text{S}_7(\text{NH}_3)_5$ is made by boiling the ammonium cobaltous salt of cobaltisulphurous acid with ammonia. With fuming hydrochloric acid, $\text{Co}_2\text{C}_2\text{S}_7(\text{NH}_3)_5$ forms $\text{Co}_2\text{C}_2\text{S}_{14}\text{ClO}_4 \cdot \text{H}_2\text{O}$; with acetic acid, $(\text{CS}_3)_2\text{Co}_2\text{S}(\text{NH}_3)_2 \cdot \text{C}_2\text{H}_3\text{O}_2 \cdot 4\text{H}_2\text{O}$; and with acetic anhydride, $\text{Co}_2\text{C}_2\text{S}_8 \cdot 5\text{NH}_3$ is formed. When the hexammino-thiocarbonate is treated with diazobenzene nitrate at 0° for 24 hrs., black prismatic crystals of $\text{Co}_2\text{C}_2\text{S}_8(\text{NH}_3)_6 \cdot \text{H}_2\text{O}$ are formed, and with nitrous oxide, cobalt triaminotritrite is formed. This is taken to prove that no ammonia is combined between the cobalt and sulphur, for, if this were the case, groups of the constitution $\text{CoNH}_3 \cdot \text{S} \cdot \text{NH}_3\text{Co}$ or $\text{Co} \cdot \text{NH}_3 \cdot \text{S} \cdot \text{C}$ would be formed, and the compound $\text{C}_2\text{S}_7\text{Co}_2(\text{NH}_3)_5$ should give the reactions of hydrogen sulphide or thiocarbonic acid. Brownish-red crystals of $\text{Co}_2\text{C}_2\text{S}_7(\text{NH}_3)_5 \cdot 2\text{H}_2\text{O}$ are produced when cobaltic hydroxide is treated at 10° with 10 per cent. aq. ammonia and carbon disulphide; if this mixture is allowed to stand 4-5 days, black prisms of $\text{CoCS}_3 \cdot \text{H} \cdot 3\text{NH}_3$ are formed.

According to J. J. Berzelius, an aq. soln. of calcium thiocarbonate gives a dark brown precipitate with a soln. of a platinic salt; the precipitate is soluble in an excess of the thiocarbonate, forming a brownish-yellow soln.; when dried, the precipitate is nearly black, and is presumably platinic thiocarbonate. When heated it gives off carbon disulphide, and sulphur, and leaves platinum sulphide behind. According to K. A. Hofmann, iridium thiocarbonate and rhodium thiocarbonate are formed in a similar way. These three thiocarbonates readily combine with ammonia. Hydrated platinum diamminothiocarbonate, $\text{PtCS}_3(\text{NH}_3)_2 \cdot 12\text{H}_2\text{O}$, is obtained from potassium platinous chloride, conc. ammonia, and carbon disulphide. It crystallizes in long, red needles, is insoluble in cold water, ammonia, or sodium hydroxide, and gives up its water of crystallization when allowed to remain in vacuo over sulphuric acid. It gives no coloration with sodium nitroferrocyanide, nor a mercaptan nor methyl sulphide when boiled with methyl iodide. Under certain conditions, which have not yet been determined, platinum tetramminothiocarbonate, $\text{Pt}_2\text{Cl}_2(\text{NH}_3)_4\text{CS}_3$, is formed, and crystallizes in slender, red needles; and platinum aminothiocarbonate, $\text{C}_2\text{S}_6\text{PtNH}_3$, is obtained from ammonium platinum chloride, ammonia, and carbon disulphide; it crystallizes in lustrous, black crystals, and is easily soluble in dil. sodium hydroxide.

§ 44. Perthiocarbonates

Perthiocarbonates analogous to the percarbonates prepared by electrolysis have not been obtained, but salts corresponding with the percarbonates produced by acting on the carbonates with hydrogen dioxide have been made. Thus, *A. Gélis* found that when carbon disulphide is treated with sodium disulphide, Na_2S_2 , sodium perthiocarbonate, Na_2CS_4 , is obtained; and a similar compound was made by the direct action of sulphur on the thiocarbonates. There is no analogous mode of preparation with the percarbonates, and this fact brings out the greater tendency of sulphur atoms to form chains than is evinced by oxygen atoms. *E. W. Yeoman* prepared sodium perthiocarbonate in the following manner:

Sodium (2.3 grms.) was dissolved in 40 c.c. of absolute alcohol and mixed with a soln. of 2.3 grms. of sulphur in 40 c.c. of alcohol so as to form an alcoholic soln. of sodium sulphide, which was converted into the disulphide by the addition of 3.2 grms. of sulphur. A slight excess of carbon disulphide was added, the colour of the soln. changing from yellow to red. On addition of ether to this perthiocarbonate soln. a reddish-yellow oil was precipitated, which slowly solidified to a microcrystalline mass of brownish-yellow needles. On keeping, the filtrate deposited a further amount in nodular aggregates of prismatic, doubly refracting needles. The crystalline mass was collected, washed with ether in an atm. of hydrogen, and finally dried at 60° in a stream of the same gas.

Alternatively, the sodium disulphide required may be prepared by the direct addition of sulphur to the sodium hydrosulphide without addition of a second mol. of sodium ethoxide, the disulphide being then formed with the evolution of hydrogen sulphide. The salt is very deliquescent, and readily dissolves in water, forming a yellow soln.; it also dissolves in alcohol, from which it is precipitated by ether or benzene. The salt is stable in dry air free from carbon dioxide, but it is quickly decomposed in moist air owing to the loss of carbon disulphide and the oxidation of

residue mainly to thiosulphate: $\text{Na}_2\text{CS}_4 = \text{Na}_2\text{S}_2 + \text{CS}_2$; and $\text{Na}_2\text{S}_2 + 5\text{H}_2\text{O} + 30\text{Na}_2\text{S}_2\text{O}_3 \cdot 5\text{H}_2\text{O}$. When heated, the perthiocarbonate behaves like the thiocarbonate excepting that sodium disulphide takes the place of the monosulphide. The aq. soln. can be kept unchanged for a long time in the absence of air; but if air has access, carbon disulphide and sodium thiosulphate are formed. When the air-free soln. is heated in a sealed tube, sodium thiosulphate is formed; some sulphur separates when the tube is cooled, and much hydrogen sulphide escapes on opening the tube. The reactions, in the main, resemble those with sodium thiocarbonate. If an aq. soln. of the salt be distilled in the absence of air, it loses its carbon disulphide; if a current of air be passed through the boiling soln. some carbonate is formed—there was never a 50 per cent. conversion to the carbonate. The salt is quickly decomposed by carbon dioxide, forming carbon disulphide, a carbonate, sulphur, and hydrogen sulphide. With sulphur dioxide, thiosulphate, sulphur, and carbon disulphide are formed: $2\text{Na}_2\text{CS}_4 + 3\text{SO}_2 = 2\text{Na}_2\text{S}_2\text{O}_3 + 3\text{S} + 2\text{CS}_2$. A soln. of the salt does not dissolve sulphur. The additional sulphur atom in the perthiocarbonates is readily removable by reagents which have a direct action on sulphur, such as hydrocyanic acid or sodium cyanide. When excess of the latter reagent is added to the pure yellow soln. of the perthiocarbonate the colour soon changes from yellow to the characteristic red of the thiocarbonates, the additional atom of sulphur being removed and converted by the cyanide into thiocyanate. E. W. Yeoman prepared **potassium perthiocarbonate**, $\text{K}_2\text{CS}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$, by the method employed for the sodium salt. Attempts to remove the water resulted in the decomposition of the salt. The reactions resemble those with sodium perthiocarbonate. H. von Halban and co-workers examined the spectra of soln. of **perthiocarbonic acid**, H_2CS_4 , in chloroform, toluene, and light petroleum, and of the sodium salt in aqueous soln. They also measured the rate of decomposition of the acid in several organic solvents.

E. W. Yeoman prepared **ammonium perthiocarbonate**, $(\text{NH}_4)_2\text{CS}_4 \cdot \text{H}_2\text{O}$, by converting a 20 per cent. alcoholic soln. of ammonia into the hydrosulphide and adding the exact amount of sulphur to convert it into the disulphide, $(\text{NH}_4)_2\text{S}_2$, all the operations being made in the absence of air. On addition of carbon disulphide, the perthiocarbonate was immediately precipitated as a yellow, crystalline solid. The crystals were collected, washed with dry ether with the usual precautions, and the ether was removed as completely as possible in a current of hydrogen at the ordinary temp. The anhydrous salt was obtained in monoclinic or triclinic crystals by allowing an alcoholic soln. of the monohydrate to evaporate spontaneously at ordinary temp. The salt decomposes completely when heated to 100° in a current of hydrogen and leaves a residue of sulphur. The general behaviour of the perthiocarbonate resembles that of the thiocarbonate. At the ordinary temp., aq. soln. are only very slowly converted into the thiocyanate, excess of ammonia hastening the reaction. As with the trithiocarbonate, the conversion to thiocyanate is complete if the salt is heated in a sealed tube with alcoholic ammonia at 100° . The soln. of both ammonium trithiocarbonate and perthiocarbonate are very unstable, partly because of the well-known change which ammonium trithiocarbonate undergoes, whereby it loses hydrogen sulphide in two stages, passing successively into ammonium dithiocarbonate and ammonium thiocyanate, and partly on account of the ready manner in which it undergoes complete dissociation into ammonia, hydrogen sulphide, and carbon disulphide.

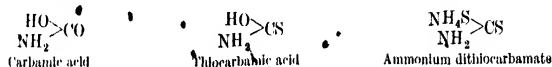

E. W. Yeoman prepared a basic salt, **calcium tetrahydroxyperthiocarbonate**, $\text{CaCS}_4 \cdot 2\text{Ca}(\text{OH})_2 \cdot 8\text{H}_2\text{O}$, by converting calcium oxide into an aq. soln. of the polysulphide, and passing a current of hydrogen sulphide sat. with carbon disulphide vap. On evaporating the soln. in vacuo, dark red needles of the basic salt were formed. With alcoholic soln., an impure perthiocarbonate was formed. E. W. Yeoman succeeded in preparing soln. of **strontium, barium, and magnesium perthiocarbonates** by allowing aq. soln. of the thiocarbonates to dissolve in sulphur. Attempts to make the solids were not successful.

§ 45. The Thiocarbamic Acids and the Thiocarbamates

The analogy between carbonic acid and thiocarbonic acid, and between the carbonates and the thiocarbonates, extends also to carbamic acid (p. 20, 34) and the thiocarbamic acids:

In harmony with the observations on the thiocarbonic acids, there are three possible thiocarbamic acids, namely:

F. Salomon¹ made **methyl thioncarbamate**, $\text{NH}_2\text{CS.OCH}_3$; and H. Debus, G. Chancel, and F. Salomon made **ethyl thioncarbamate**. These esters are derivatives of thiocarbamic acid. E. Blankenhorn made **methyl thiolcarbamate**; and A. Pinner, F. Salomon, and A. Fleischer, **ethyl thiolcarbamate**, which are derivatives of thiolcarbamic acid. M. Berthelot made **ammonium thiolcarbamate**, $\text{NH}_2\text{CO.SNH}_4$, by passing gaseous carbonyl sulphide into alcoholic ammonia; E. Schmidt and A. Kretschmar, by passing the same gas into aq. ammonia at 0°. The salt forms colourless crystals, very soluble in water, moderately soluble in alcohol, and insoluble in ether. The dry salt becomes yellow on exposure to air, forming ammonium thiocyanate. According to E. Mulder, water at 100° converts ammonium thiolcarbamate into ammonium hydrosulphide and hydrocarbonate. The dry salt forms thiourea when heated in a sealed tube at 135°, or when its cold aq. soln. is treated with lead hydroxide. Ferric chloride forms a red liquid which ultimately yields a precipitate. A. Fleischer found that mercuric oxide, in the cold, converts ammonium thiolcarbamate into ammonium cyanate. When the ammonium salt is treated with acids, **thiolcarbamic acid**, $\text{NH}_2\text{CO.SH}$, is liberated, but it immediately decomposes into carbonyl sulphide and ammonia.

W. C. Zeise² prepared **ammonium thiocarbamate**, or **ammonium dithiocarbamate**, $\text{NH}_4\text{S.CS.NH}_2$, by the action of carbon disulphide on alcoholic ammonia—*vide supra*, ammonium thiocarbonate. H. Debus said that the best yield is obtained by working at 10°–15° with not too conc. soln. E. Mulder passed the gas from 150 grms. of ammonium chloride and 300 grms. of quicklime into 600 parts of 95 per cent. alcohol and 96 grms. of carbon disulphide, and crystallized at about 30°; in this way no crystals of ammonium thiocarbonate were formed. It is also formed when ammonium thiocarbonate is heated. M. Freund and G. Bachrach obtained a 55 per cent. yield by mixing 50 grms. of 10 per cent. alcoholic ammonia dil. with 5 grms. of 96 per cent. alcohol, and 12 grms. of carbon disulphide. G. Inghilleri prepared ammonium dithiocarbamate by heating 6 grms. of carbon disulphide and 8 grms. of ammonium carbonate in a sealed tube for 6 hrs. at 100°–110°: $\text{CS}_2 + (\text{NH}_4)_2\text{CO}_3 = \text{H}_2\text{O} + \text{CO}_2 + \text{NH}_4\text{S.CS.NH}_4$. Ammonium thiocarbamate furnishes citron-yellow, prismatic crystals. If derived from 95 per cent. alcohol, said E. Mulder, the crystals are but feebly coloured, and with 85 per cent. alcohol, colourless needles are obtained. W. C. Zeise said that when freshly prepared the

crystals have no smell, but after standing in air for some time, they smell of ammonia and hydrogen sulphide; sulphur, water, and ammonium thiocyanate are formed. In moist air, said H. Debus, the crystals give a turbid liquid which consists almost wholly of ammonium thiocyanate. If air is excluded, W. C. Zeise found that the undried crystals pass in some weeks into hydrogen sulphide and ammonium thiocyanate. When heated, the crystals melt with some bubbling; at 150°, much ammonia, probably mixed with cyanogen and nitrogen, is evolved, and carbon disulphide, ammonium thio carbonate, and thiocyanate are formed; and at 200°, the mass leaves a brown residue. The crystals are readily soluble in water, forming a yellow soln. J. H. Gladstone found a soln. of the salt in 18.71 eq. of water has a sp. gr. 1.091 at 10°, and the refractive indices 1.4171 with the *A*-line, and 1.4254 with the *D*-line. W. C. Zeise, and M. Freund and G. Bachrach found that chlorine, or ferric chloride, converts ammonium thiocarbamate into thiocarbamide disulphide, $(\text{NH}_2\text{CS})_2\text{S}_2$. P. Klason observed that the same product is obtained by the action of a hydrochloric acid soln. of iodine. According to W. C. Zeise, when hydrochloric acid or sulphuric acid, dil. with 8 parts of water, is mixed with the salt dissolved in 12 parts of water, the mixture becomes turbid in a few minutes; the more dil. the soln., the longer is the appearance of the turbidity delayed. If the soln. be allowed to stand in a closed vessel for 12 hrs., carbon disulphide, and an ammonium salt, and probably hydrogen cyanide, are formed. If the aq. soln. be heated, or if the alcoholic soln. be allowed to stand or warmed, carbon disulphide, hydrogen sulphide, and ammonium thiocyanate are formed. For the action of hydrochloric acid, *vide infra*. A. W. Hofmann found that with an alcoholic soln. of iodine, ammonium thio carbonate furnishes ethyl thiocyanate, and ethylamine, $\text{C}_2\text{H}_5\text{NH}_2$. W. C. Zeise said that ammonium dithiocarbamate dissolves very sparingly in cold alcohol, but is more soluble in warm alcohol. E. Mulder said that the salt is insoluble in alcohol. A. Fleischer found that sulphur separates from the alcoholic soln., and W. C. Zeise observed that ammonium dithiocarbamate, thiocyanate, and thiosulphate are formed when the alcoholic soln. is warmed. The salt is insoluble in petroleum. H. Debus said that when ammonium dithiocarbamate is warmed with potassium hydroxide, potassium thiocyanate and hydrosulphide, ammonia, and water are formed. A. Fleischer said that the salt is desulphurized by mercuric oxide.

According to H. Debus, a soln. of ammonium thiocarbamate with cerium sulphate furnishes colourless needles which contain no cerium; uranium nitrate soln. is coloured blood-red; with soln. of arsenious acid, antimony pentachloride, stannous chloride, or bismuth nitrate, white or yellow precipitates are obtained; mercuric chloride soln. gives a white precipitate—probably mercurous chloride—nickel sulphate soln. gives a yellowish-green precipitate; and platinum chloride a brown precipitate. J. Klein discussed the possible applications of the salt in analytical chemistry. Cupric thiocarbamate, $\text{Cu}(\text{S.CS.NH}_2)_2$, is precipitated as a yellow powder insoluble in water; zinc thiocarbamate, $\text{Zn}(\text{S.CS.NH}_2)_2$, as a white mass; and lead thiocarbamate, $\text{Pb}(\text{S.CS.NH}_2)_2$, as a white mass which blackens when boiled with water. A number of complex thiocarbamates were made by H. Goldschmidt and L. Schulhof, S. M. Losanitsch, A. W. Hofmann, and G. Ponzio. M. Delépine made complexes with sodium, copper, silver, barium, zinc, mercury, lead, cobalt, and nickel thiocarbamates; and L. Compin, with copper, cobalt, and nickel thiocarbamates.

If hydrochloric acid be slowly added to a conc. soln. of ammonium thiocarbamate, cooled below 10°, the free acid—dithiocarbamic acid, HS.CS.NH_2 —separates out in colourless needles which are very soluble in water, alcohol, and ether. The alcoholic soln. of the acid decomposes into carbon disulphide and the ammonium salt; and the aq. soln. when warmed decomposes into hydrogen sulphide, and thiocyanic acid. E. Mulder found that when heated the acid forms the ammonium salt, $\text{HS.CS.NH}_2 = \text{CS}_2 + \text{NH}_3$; and $\text{NH}_3 + \text{HS.CS.NH}_2 = \text{NH}_4\text{S.CS.NH}_2$.

According to G. B. L. Smith and F. Wilcoxon³ azido-dithiocarbamic acid,

HS.CS.N_3 has been prepared by the treatment of conc. soln. of the sodium salt with conc. hydrochloric acid. It is a white or very pale yellow, crystalline solid; it crystallizes in the monoclinic system, has a strong double refraction, and is readily soluble in non-aqueous solvents. It has the characteristic properties of a strong acid, and its strength approaches that of hydrochloric acid. It is easily oxidized by various oxidizing agents, yielding the free halogenoid, **azido-dithiocarbonate** $(\text{S.CS.N}_3)_2$. In the solid form, the acid is very sensitive to both shock and to heat. It undergoes spontaneous decomposition at the ordinary temp., in keeping with the laws of unimolecular change. In the dry state, this reaction is catalysed by an intermediate product or by the thiocyanic acid formed, but not in aqueous soln. The decomposition may be represented by the equation $\text{HS.CS.N}_3 = \text{HSCN} + \text{S} + \text{N}_2$. The solid product formed consists of polymerized thiocyanic acid and free sulphur.

The chapter on carbon does not include those hydrocarbons and their derivatives commonly but arbitrarily admitted into inorganic chemistry; the cyanides and complex cyanides; nor does it include the combustion of the hydrocarbons. These subjects may later be discussed in a supplementary volume.

CHAPTER XL

SILICON

§ 1. The History of Silicon

It was the general opinion of the early Greek philosophers that minerals and earths were all formed from water. Thus, about 315 B.C., Theophrastus opened his essay—*Ἐπεὶ λίθων*—*On Stones*:

Everything formed in the earth has its origin either from water or from earth. Water is the base of all the metals.

Theophrastus' term *κρυστάλλος*, translated *crystallus* in Pliny's *Historia naturalis* (37. 9, A.D. 77), is derived from the Greek word for ice; and it was specifically applied to the mineral now known as *rock crystal* or *quartz* because

Crystal assumes a concrete form from excessive congelation. At all events, crystal is to be found only in places where the winter snow freezes with the greatest intensity; and it is from the certainty that it is a kind of ice, that it has received the name which it bears in Greek.

In his *Bibliotheca historica*, Diodorus Siculus made the counter-guess that although rock crystal is formed from the purest water, it is not cold. Rather has the *divinus calor* or solar heat made water so hard and dry that it has become crystal. Pliny's guess, however, was most generally accepted.¹ G. Agricola, for instance, said that "rock crystal is not ice, but a denser product of cold." The idea was combated by A. B. de Boodt,² J. J. Becher, and R. Boyle in the seventeenth century. Thus, the last-named said:

I found the weight of crystal to be to that of water of equal bulk as two and two-thirds to one: which by the way shows us how groundlessly many learned men, as well ancient as modern, make crystal to be but ice extraordinarily hardened by long and vehement cold, whereas ice is, bulk for bulk, lighter than water (and therefore swims upon it) and (to add that objection against the vulgar error) Madagascar and other countries in the Torrid zone abound with crystal.

The history of the discovery of glass is described later. The ancients knew very well that a clear glass can be made by fusing sand or rock crystal with salts of potassium or sodium. J. B. van Helmont³ noticed that such a glass can be slowly dissolved in water, and that the addition of aqua fortis to saturate the alkali, precipitates the original quantity of siliceous earth. J. R. Glauber called the aq. soln. of the fused alkali and sand—*oleum silicum*, or *liquor silicum*; and J. N. von Fuchs, *Wasserglas* (q.v.).

The high temp. fusibility and the resistance of silica to chemical reagents has greatly retarded the development of the chemistry of silica. C. W. Scheele's discovery of hydrofluoric acid, in 1771, proved a veritable touchstone to the chemistry of silica, but even then, progress was and is very slow. Silica has been identified with the *terra vitrescibilis* of J. J. Becher⁴ (1. 1, 15). In 1666, O. Tachenus pointed out that, unlike earths, silica has acidic properties, for it unites with alkalies, and shows no tendency to neutralize the acids. The feebly acidic qualities of silica were emphasized further by J. Smithson, and J. W. Döbereiner. J. J. Berzelius (1811), indeed, showed that silica unites with the bases in definite proportions, forming salts of silicic acid; and that siliceous minerals are to be regarded as definite salts of this acid. T. Bergman separated silica from siliceous

earths by fusing them with alkali carbonate or hydroxide, and treating the product with dil. acid—insoluble silica, and soluble alkali salts were formed.

Towards the end of the eighteenth and the beginning of the nineteenth centuries, G. L. L. de Buffon,⁵ P. J. Macquer, and many other chemists regarded silica as a primitive earth, for it was argued: *la silice est la plus homogène, la plus simple, et la plus élémentaire des terres*.⁶ This view was favoured by the infusibility of silica, and the resistance which it offers to attack by reagents generally. Some aluminous earths, however, were confused with silica. J. H. Pott,⁶ in his memoir: *Ueber den terris vitrescentibus* (1746), emphasized his belief that the chief constituent of the vitrifiable rocks was a peculiar earth which could not be converted into lime, but which, when fused with alkalies, forms a *terra alcalina* which is precipitated by a small amount of acid, and can be dissolved in an excess of vitriolic acid producing what he called *terra sequeptica*. The work of J. H. Pott was extended by A. Baumé, and J. F. C. Meyer. A. Baumé showed that only freshly precipitated silica is soluble in the acid:

Il faut prendre tandis qu'elle est en bouille, et avant qu'elle ait été séchée; car lorsqu'on l'a fait sécher, les parties se sont réunies et agglutinées entre elles par l'attraction; cette terre alors ne plus se dissout.

F. A. Cartheuser, C. W. Scheele, and T. Bergman demonstrated clearly that although precipitated silica could be dissolved in water and acids, it was not an alkaline or calcareous earth. At the end of his essay: *De terra silicea* (Upsala, 1779), T. Bergman concluded that:

Those earths are called primitive which cannot be resolved into such as are more simple, and derivative earths are those which are composed of two or more primitive earths intimately united. . . . In mineralogy, siliceous earth may be considered to be primitive until by apt experiments, both analytic and synthetic, it be demonstrated that the base of this earth entirely agrees with one already known. . . . If the question be asked whether siliceous earth be altogether simple and homogeneous, the proper answer would be in the negative, for it appears plainly to consist of two principles, namely, fluor acid and something derived from water.

Thus, T. Bergman believed that siliceous earth is primitive, but his confidence was shaken because he added, "but not altogether primitive." This doubt was a result of his repetition of some experiments by C. W. Scheele,⁷ who, in 1771, regarded silica earth as a compound of hydrofluoric acid with water because, as A. S. Margraaf had shown in 1768, the gas obtained when fluorspar is heated in a glass retort with sulphuric acid, gives a precipitate of silica when passed into water. It was, however, proved by J. C. F. Meyer that no silica is obtained if the sulphuric acid be heated with fluorspar in a lead retort; and C. W. Scheele, and J. C. Wiegleb then demonstrated that no silica is obtained if the materials used in the preparation of the gas are kept out of contact with any substance containing silica.

In 1787, A. L. Lavoisier⁸ assumed silica to be an oxide of an unknown metal. About 1808, J. J. Berzelius mentioned in a letter to H. Davy that in making an analysis of cast iron, he found it contained the metal of silex, and that on oxidation, this metal took up nearly half its weight of oxygen; he also succeeded in decomposing silica by heating an admixture of silica, iron, and charcoal. This product ultimately proved to be an alloy of silicon and iron, namely, *ferrosilicon*. In 1809, H. Davy attempted to isolate the metal by the electrolysis of silica, or by reduction with potassium at a red heat. He said: Had I been so fortunate as to have obtained more certain evidences of the metallic substance I was in search of, I should have proposed for it the name *silicium*. No definite result was obtained by J. Mantell, in 1818, although in 1809, J. L. Gay Lussac and L. J. Thénard heated potassium in the vapour of *le gaz fluorique silice*, and noted that the reaction was attended by the development of much heat and light; a large quantity of the gas was absorbed, and very little hydrogen was produced; the potassium disappeared and there remained *une matière solide dont la couleur est brun rougeâtre* which was not examined further. In 1823, J. J. Berzelius produced the element by reducing potassium

fluosilicate, K_2SiF_6 , with potassium, and he also determined its chief properties—*vide infra* at. wt. silicon. J. J. Berzelius called his product *Kiesel*, but this term has not been adopted.

§ 2. The Occurrence of Silicon and Silica

Silicon does not occur free. Silicon is next to oxygen the most abundant element in Nature. It occurs in all silicate minerals, and it is the characteristic element of all important rocks outside the carbonates. F. W. Clarke's estimate of the mean percentage mineralogical composition of about 700 igneous rocks is quartz, 12.0; feldspars, 59.5; hornblende and pyroxene, 16.8; mica, 3.8; and accessory minerals, 7.9. According to F. W. Clarke's estimates, 27 per cent. of the earth's lithosphere is combined silicon, and 47.33 per cent. is oxygen. Again, 85.79 per cent. of the earth's hydrosphere is oxygen; and the average in the lithosphere, hydrosphere, and atmosphere is 50.02 per cent. oxygen, 25.80 per cent. silicon. F. W. Clarke further estimates that on the average, 59.79 per cent. of the igneous rocks; 58.10 per cent. of the shales; 78.33 per cent. of the sandstones; and 5.19 per cent. of the limestones in the earth's crust consist of silica—free or combined. The weighted average for the lithosphere is 59.77 per cent. of silica.

Silicon occurs as free silica, silicon dioxide, in the form of quartz, and, as such, is one of the most common and most abundant minerals on the earth's crust; it forms whole mountain ranges in Scotland, Ireland, North Wales, Shropshire, and numerous other parts of the earth. Some of the water-worn quartz grains in the riverbeds of Minas Geraes (Brazil) are transparent and colourless, and they are used extensively as *Brazilian pebbles* in the manufacture of spectacle and other lenses. Similar pebbles are found in Madagascar. The clear and transparent varieties of

quartz were called *crystal* by the ancient Greeks; and to-day they are known as **rock crystal**—*crystal de roche*, or *Bergkrystall*; while the variety which is white, and translucent or opaque is common **quartz**. Some of the glittering rock crystals are called "diamonds" in particular districts—e.g., *Bristol diamonds*, *Marmaroscher Diamanten*, etc. During the cinquecento period—sixteenth century—transparent and colourless quartz was made into vases, bowls, etc., and elaborately engraved, and this mineral was similarly treated by the ancient Greeks and Romans. Rock crystal was probably the sixth precious stone—under the name *adamas* (diamond)—described in *Exodus* (28. 18; 39. 11) as ornamenting the breast-plate of the high priest of the children of Israel.

Nature furnishes some beautiful specimens of crystalline quartz. A single crystal weighing nearly a ton has been reported at Calaveras (U.S.A.), and some fine crystals have been found in many other places—Dauphiné, Savoy, St. Etienne-la-Varenne, the Apuan Alps, the Alps, Snowdon in Wales, Tintagel in Cornwall, etc. Quartz from different localities often shows differences in colour, translucency, and structure; there are a great number of varieties to which special names were applied before it was known that they belonged to the same mineral species, and composed of the same fundamental substance—silica. Some of these varieties still retain their old trivial names, and some are important gem-stones.

For example, the **amethyst**, *amethystine*, or *amethyst quartz* has a bluish-violet or purple colour. It obtains its name from α , not; and $\mu\epsilon\theta\omega$, to intoxicate, because it was fabled to possess some quality which prevented intoxication by wine drunk from amethyst vessels. A sample from Minas Geraes (Brazil) analyzed by H. Rose² yielded 97.5 per cent. of silica; 0.25 per cent. of alumina; 0.5 per cent. of iron oxide; and 0.25 per cent. of manganese oxide. It has been suggested that the colour is due to the last-named oxide, but this has not been definitely decided. C. F. Rammelsberg's analysis of a Brazilian sample showed no manganese, and he assumed that the colour is due to a compound of iron and soda. The colour is not destroyed by heating the mineral to about 300°, but if heated to redness, the colour becomes yellow when cooled. W. Hermann found that smoky quartz, amethyst, and citrine lose their colour when heated in oxidizing or reducing gases, and therefore the tinctorial agent is not an oxide of the heavy metals. T. L. Watson and R. E. Board, T. H. Holland, regarded the colour as due to fine rutile inclusions; and E. F. Holden, to hydrated colloidal ferric oxide. **Rose quartz** has been stated to owe its rose-red colour to manganese; but this is not certain. The colour becomes paler when exposed to light. J. N. Fuchs² attributed the colour to the presence of 1.0 to 1.5 per cent. of titanic oxide; W. Hermann, and E. F. Holden, to tervalent manganese; and R. Brauns, P. Berthier, K. von Kraatz-Koschlag, and T. L. Watson and R. E. Board, to organic matter. A. Nabl found traces of iron and sulphur in amethysts, and showed that citrine had the absorption spectrum of iron oxide; accordingly, he assumed that the colour was produced by iron thiocyanate, but this is not likely. E. Weinschenk opposed the views that the colouring matter is organic, or titania alone, though he said it might be due to small amounts of sesquioxides of titanium, tin, or zirconium. He obtained a red colour with alumina and titanium. It is not improbable that the colour of the amethyst and rose quartz is really due to manganese. E. F. Holden found a pink crystal to be coloured by hæmatite inclusions of microscopic dimensions. The decolorization of rose quartz by heat was studied by W. Hermann, K. Simon, and E. F. Holden. **Yellow quartz**, or *citrine*, is the colour of topaz, and has hence been called *false topaz*. E. F. Holden found a sample of citrine to be coloured by submicroscopic particles of hydrated ferric oxide. **Smoky quartz**, or *quartz fumée* or *Rauchquarz*, owes its yellow, brown, or black colour to the presence of organic matter or hydrocarbons. Sometimes the quartz is so rich in organic matter that it has a nutty smell when warmed—*stink quartz* or *fœtid quartz*. K. von Kraatz-Koschlag and L. Wöhler found 0.04 per cent. of carbon, and 0.0073 per cent. of hydrogen in a sample of smoky quartz. R. J. Strutt found smoky quartz to be optically turbid, scattering light very strongly; but C. V. Raman showed that with ultra-red rays, smoky quartz is as transparent as colourless quartz. A. Forster made some observations on this subject. B. L. Vanzetti found some specimens exhibit Tyndall's phenomenon, and the coloration disappears at 300°. The lighter coloured varieties of smoky quartz were possibly those called *marmorion* by Pliny. Cut specimens of yellow and brown smoky quartz from Banffshire are known as *Cairngorm*. **Milky quartz**, or *quartz laiteux*, or *quartz en chemise*, or *Milchquarz*, owes its opalescence to the presence of innumerable cavities containing, according to D. Brewster,⁴ an oily liquid; sometimes the cavities contain a bituminous fluid and at other times water and air-bubbles.

The colour of common quartz is very varied, and is usually due to the presence of foreign particles enclosed in the crystals. For instance, *ferruginous quartz* or *Eisentiesel* is coloured either red by ferric oxide, or yellow by hydrated ferric oxide; *aventurine*

quartz contains scales of mica or hematite which give it a spangled appearance. *Cat's paw*, *œil de chat*, or *Katzenauge* is a translucent variety of quartz with numerous fine areas of asbestos or actinolite arranged parallel to one another, which cause a curious iridescent reflection from the surface with a play of colours moving across the surface as the stone is turned. Cat's-eye quartz is sometimes called *crocidolite*—*κροκίς*, wool—at this name is usually reserved for a variety of chrysoberyl.

There are two native forms of crystalline silica, *tridymite* and *cristobalite*, which are quite different from quartz and from each other, so that silica is at least trimorphous. Tridymite is found in the more siliceous igneous rocks which have crystallized from molten magmas, in volcanic lavas, and in some meteorites. Cristobalite is comparatively rare; it sometimes accompanies tridymite. Cristobalite has been found in Cerro San Cristóbal (Pachuca, Mexico), St. Vincent Martinique lava, 1902-3), Mont-Doré (Plateau Central, France), Olokele Canyon Kauai, Hawaiian Islands), Rhenish Prussia, Tuscan Springs (Tahama County, Cal.), and Jamestown (Toulumne County), in the obsidian of Yellowstone National Park by A. F. Rogers; ⁵ and in a meteorite found in Kendall County (Texas) by A. F. Rogers. Tridymite has been found in the trachyte of the Euganean Hills, near Padua; ⁶ in the trachyte of Drachenhfels; in rocks in Scotland, Laacher See, Phlegrean Fields, Moezar (Hungary), Auvergne, Demarest (Persia), Aden, Guatemala, New Zealand, etc.

The different forms of quartz can be arranged in three groups: (1) The crystalline group described above; (2) the chalcedonies which were once thought to be amorphous, but which are really partially crystalline—cryptocrystalline—*κρυπτός*, hidden; and (3) the hydrated silicas or opals. The name *chalcedony* is applied to various forms of concretionary silica which appear to be made up of quartz, and hydrated silica of the nature of opal. Chalcedony is translucent or opaque; and either white, grey, yellow, brown, or blue. Although crystalline, chalcedony has not the external form characteristic of crystals, but rather occurs in mammillary, botryoidal, globular, or stalactitic masses.

The amount of water in different varieties of chalcedony varies from less than one up to about five per cent., and this in conjunction with the general relations which chalcedony bears to quartz and to opal, confirms C. Hintze's view ⁷ that chalcedony is a mixture of crypto-crystalline quartz and a hydrated form of silica related to opal. Assuming that the sp. gr. of opal is 2.15 and of quartz 2.65, the corresponding proportions of these two assumed components of chalcedony can be calculated from the observed sp. gr. Chalcedony can be dyed black, red, blue, green, and yellow.⁸ Chalcedony appears to have been named after *Χαλκηδών* or *Καλχηδών*, places in Asia Minor, whence it was once obtained. All the varieties of chalcedony referred to by Pliny and Theophrastus have not been clearly identified with those recognized to-day. The so-called *quartzine* and *luteite* are varieties of chalcedony.⁹

The mineral *carnelian* is a variety of chalcedony which is translucent and of a red colour, hence the name *caro*, *carnis*, flesh; *sard*—from Sardes in Lydia, or Sardo the Greek name for Sardinia—is an early name for carnelian, but is now applied to a pale or dark brown translucent chalcedony; *plasma*—*πλάσμα*, image—is a variety of chalcedony coloured green by enclosures of green earth or chlorite, and it resembles green jasper. *Heliolite* or *bloodstone* is a form of *plasma*, and is a mixture of earthy chlorite and chalcedony. It is usually green in colour with small spots of iron oxide, blood-red in colour. The derivation of the name—from *ἥλιος*, the sun; *τροπή*, a turning—refers to the old supposition that if the mineral be immersed in water it will change the image of the sun blood-red. Another form of bloodstone is hematite, not silica. *Chrysoprase*—*χρυσός*, golden; *πράσιον*, a leek—is an apple-green or grass-green variety of chalcedony found in Silesia. According to M. H. Klaproth's analyses,¹⁰ the colouring agent is nickel oxide—approximately one per cent. *Agate*—from Achates, a river in Italy where specimens were found and now called the Drillo—is a variety of chalcedony sometimes with alternate zones or layers—light and dark. S. S. Bhatnagar and K. K. Mathur ¹¹ discussed the formation of these rings, and prepared artificially banded silica gel by allowing ferric, cobalt, or nickel salt soln. to diffuse into silica hydrogel—vide 1. 10, 6. A translucent, white or bluish-white variety, having included in it metal oxides causing brown, red, or black dendritic forms, is called *moon agate*, or *tree agate*, or *mocha-stone*. The variety of agate called *onyx*

--*onyx*, a finger nail—has concentric zones alternately white and dark brown or grey; *sardonyx* is a variety of onyx with white and reddish-brown layers. *Flint*—also called *silex*, or *la pierre à feu*, or *Feuerstein*—is allied to chalcedony. It has a conchoidal fracture, and the colour varies from grey to black. It is of organic origin and often contains sponge spicules. The nodules of flint found by primitive man were shaped into various forms so that they could be conveniently held in the hand, and used as implements or weapons. Man, the tool-maker, thus inaugurated the Stone Age, estimated to have been at least 80,000 years ago. In the earlier stages of the Stone Age—the Palæolithic Period—the flints were roughly shaped by chipping; while in the later stages—the Neolithic Period—the flints were ground and polished. *Chert* or *hornstone* is a compact variety of chalcedony, and, like flint, is of organic origin. *Lydian stone*¹²—also called *lydile*, or *touchstone*—is a grey or velvety-black flinty rock or siliceous slate used by jewellers for testing the purity of gold. The metal under investigation is rubbed on the polished surface of the stone, and the colour of the streak of metal, particularly when touched with acid, enables those experienced in the colour of the streaks to estimate the proportion of gold in the alloy. This stone was employed by the ancients under the name *lapis lydius* or *lapis basanitis* for the same purpose. The stone was formerly obtained from Lydia (Asia Minor), but it is now obtained from other localities. A sample analyzed by J. B. A. Dumas gave:

SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	CaO	MgO	K ₂ O	Na ₂ O
84.40	5.25	1.15	0.43	0.13	0.69	0.70

with sulphur and phosphorus about 0.06 each; water, 0.7; and organic matter, 4.65 per cent. *Jasper* is a siliceous rock or hardened clay which occurs in masses mixed with some clay and yellow or red oxide of iron. If the yellow forms be heated, they lose water and become red. Jasper is sometimes striped green and brown, or green and red. In *Egyptian jasper* the bands occur in concentric zones. Jasper is often mentioned by ancient writers, and in the Bible.

Sandstones have been formed by the cementing together of the grains of sand, maybe under great press. The cementing agent may be argillaceous, calcareous, siliceous, ferruginous, barytiferous, etc. Special names are given to particular varieties—e.g. *ganister*, etc. In the so-called *quartzites*, the grains of quartz sand appear to have been cemented together by the infiltration of soluble silica. When thin sections are examined microscopically, the original quartz grains can usually be distinctly seen in the outline within an envelope of unfiltered and crystallized silica.¹³ In some cases, the quartz grains have recrystallized. According to T. Graham:¹⁴

The formation of quartz crystals at a low temp., of so frequent occurrence in Nature, remains a mystery. I can only imagine that such crystals are formed at an unconceivably slow rate, and from soln. of silicic acid which are extremely dil. Dilution, no doubt, weakens the colloidal character of such substances, and may therefore allow their crystallizing tendency to gain ground, and develop itself, particularly where the crystal once formed is completely insoluble as with quartz.

FIG. 1.—Section of Quartzite from the Lickey Hills (Worcestershire), under polarized light.

Sometimes the silicification of the grains has been so complete that to the naked eye the rock appears as homogeneous and compact as vein quartz, and it requires microscopic examination to reveal the agglomeration of the quartz crystals. A photograph of a thin slice from Lickey Hills (Worcestershire) is indicated in Fig. 1, as viewed under polarized light. Grains of other minerals may be cemented in the rock along with the quartz grains. Some varieties of quartzite contain over 99 per cent. silica. The *flexible sandstone* of Delhi is said by O. Mügge¹⁵ to consist of angular quartz grains which interlock or dovetail into each other so that there is a slight play between the particles. Whatever be the true explanation, the sandstone can be bent in an extraordinary manner without breaking. *La pierre élastique* or *die biegsame Sandstein* also occurs in Itacolomi, Minas Geraes, Brazil—whence the name *itacolumite*—and in several other localities, e.g. Pennsylvania, North Carolina, etc.

The non-crystalline hydrated silica called **opal** contains up to 12 per cent. of water. The colour varies from white to yellow, red, brown, grey, or blue; and the gem opal exhibits a beautiful play of iridescent colours. Selected specimens are much admired as gem stones, for they are said to "reflect all the prismatic colours in refulgent tints of indescribable brilliancy." Pliny¹⁶ says the *opalus* is made up of the glories of the most precious gems. It was called *παίδερος* or *ὀπάλλιος* by Dioscorides in his *Περὶ ὕλης ἱατρικῆς* written about 50 A.D. Some have a superstitious dread of the stone, which they suppose *porter malheur*. R. E. Liesegang discussed the hypothesis that the opalescence is due to the presence of colloidal matter.

Hyalite is a transparent colourless variety of opal; *hydropthalmos* is a variety which becomes transparent when plunged in water; and *tabaschir* is a related variety. *Geyserite* is a variety from Iceland, and other geyser localities. Analyses by R. W. Woodward,¹⁷ Forchhammer, A. Damour, C. Bickell, J. W. Mallet, A. Petzmann, etc., have been recorded by F. W. Clarke, and J. Roth. They run: SiO_2 , 79.34-94.40; Al_2O_3 , 0.69-10.96; Fe_2O_3 , 0.17-2.68; CaO , 0-1.71; MgO , 0-1.06; K_2O , 0-1.66; Na_2O , 0-3.55; SO_2 , 2-4.9; volatiles, 1.50-14.50. D. Brewster has written on this subject. The occurrence of hyalite in pitchstone has been noted by J. W. Judd, and A. Scott; and in granite, by G. Grischschinsky. Petrified wood contains much hydrated silica. Numerous other names have been applied to varieties of opaline or hydrated silica, e.g. *fire opal*, *wax opal*, *glass opal*, *ink opal*, *mother-of-pearl opal*, *iron opal*, *jasper opal*, *randanite*, *onemilite*, *resinous silica*, etc.

In his dissertation *De aquis Upsaliensibus* (Upsala, 1770), T. Bergman reported the presence of silica in this spring water, and, since then, silica has been found in most river, well, and spring waters. In 1794, J. Black¹⁸ demonstrated the relatively large proportion of silica in the volcanic springs of Iceland; R. Bunsen also made observations on the silica contents of these waters; and F. Sandberger found 0.5097 part and A. Damour 0.5195 part of silica in 1000 parts of water. A. K. Dambergis found 0.05 grm. of silica per litre in the spring water at Edepsos. C. Bickell found 0.1663-0.2373 part of silica in 1000 parts of the spring waters of Raykir; and J. Smith, 0.606 part of silica in 1000 parts of water of Rotomahana. R. Wuy found the spring waters at Reinerz, Silesia, contained from 0.04994-0.10037 part of silicic acid, H_2SiO_3 , per 100 parts. L. Colomba suggested that the silica of the fumarole water at Lipari is derived from the action of silicon fluoride on the water. G. Forchhammer¹⁹ observed the presence of silica in sea-water, and observations on this subject have been made by W. E. Ringer, R. C. Wells, etc. According to J. Murray and R. Irvine, one part of sea-water contains from one part in 220,000 to one part in 460,000; and E. Raben found 0.0002-0.0014 grm. of silica per litre. The necessary conditions for the dissolution of silica in water seem to prevail in deep-seated cavities in the earth. The water rising to the surface is cooled, and the pressure reduced. Some of the dissolved silica is then deposited at the mouth of the spring as a thick jelly. This afterwards changes into a hard white porous mass of geyserite. The Great Geyser of Iceland, for instance, is surrounded by a large mound or hillock of silica with a funnel-like cavity from which the geyser discharges. Geysers also occur in the Hot Springs of New Zealand; Yellowstone Park, U.S.A., etc. Some petrifying springs owe their special character to the silicic acid which they hold in soln. Woody tissue, for example, when immersed in such water, may be replaced by the silica. In many cases—e.g., the mineral springs at Yellowstone Park—the alkalinity of the water seems to facilitate the soln. of the silica. The alkaline silicates are decomposed by the carbon dioxide of the atmosphere and the silica is deposited in the neighbourhood as *geyserite* or *siliceous sinter*.

Silica is a regular constituent of plant ashes; the grasses and *equisetaceæ* are particularly rich in silica. According to J. L. Macie,²⁰ siliceous concretions called *tabaschir* (*vide supra*) are found in the nodes of the bamboo. F. J. Cohn discussed this product in his memoir *Ueber Tabaschir*. E. Wolff, and A. Vogel reported the ashes of barley to have 17.27-36.73 per cent. of silica; oats, 33.46-55.95; maize, 0.554; peas, 0.302; the skin of potatoes, 1.93-9.40, and the inside, 0.8-11;

tobacco leaves, 4.51-48.39; and mushrooms, 0.09-15.37 per cent. The rigidity of straw was once supposed to be due to the silica it contains, but F. Sachs²¹ found it possible to grow plants furnishing straw free from silica without affecting its rigidity; W. Knop, F. V. Jodin, and F. Höhnelt obtained similar results. E. T. von Wolff and C. Kreuzhage found a difference in the progress of grain formation, with and without silica; and A. D. Hall and A. Morrison concluded that the presence of silica increased the assimilation of phosphoric acid. C. J. Schollenberger and O. M. Shedd also noted the stimulating effects of silica on growth in soils deficient in phosphoric acid. O. Lemmermann and H. Wiesmann concluded that in the absence of phosphates, colloidal silica can take the place of phosphate. D. R. Nanjo and W. S. Shaw showed that silica is present in the plant as colloidal silica; and U. Abshagen found that in the silicification of a plant, the leaves are affected first, then the lateral sprouts, and finally the stem. Transverse sections show that the increase in silica content proceeds from within outwards. The function of the silica in the straw of most *gramineae* is not known.

Certain organisms which abound in sea and other waters probably obtain a large portion of their silica from the fine clay matter in suspension. The so-called *diatomaceous earth*, *diatomite*, or *kieselguhr* appears as a friable powder outwardly resembling chalk or clay, and is virtually a mass of the siliceous skeletons of dead diatoms, which formerly lived on the surface of pools of water, etc., and ultimately settled to the bottom along with decaying vegetable matter. The resulting diatomaceous earth is not uncommonly found in peat-bogs, and marshes on the shores of existing lakes. Some of the older deposits are consolidated—e.g. *tripoli* or *tripolite*, so named from its occurrence in Oran (Tripoli). N. Goodwin has compiled a bibliography of these earths. The skeleton of sponges is a delicate network of glass-like fibres and spicules consisting of hydrated silica analogous to opal—e.g. *Euplectella aspergillum*, or Venus' flower basket. The organisms extract the silica from sea-water. The sponges were gradually covered by accumulations of chalk, and the silica seems to have been dissolved by water percolating in the chalk, and redeposited in other parts of the limestone or chalk about other sponge spicules as irregular nodules of flint, or as bands or veins of *chert*—originally the term "flint" referred to any particularly hard rock (*Deut.* 8. 15; *Psalms* 114. 8). The photographs, Fig. 27 (and Fig. 70, 1. 11, 7), may be taken as evidence of the movement of water with silica in soln. in chalk and limestone rocks. A. M. Edwards observed that "some shells in diatomaceous earth dissolved in fresh spring water" probably from the contained ammonia.

Some parts of animals are almost free from silica, other parts contain appreciable amounts. E. C. F. von Gorup-Besanez found appreciable amounts in animal tissues, feathers, etc. The ash of hen's blood is reported²² to have 1.24 per cent. of silica; the ash of the feathers of flesh-eating and insect-eating birds, 27 per cent. of silica; fish-eaters, 10.5 per cent.; and grain-feeders, 40 per cent. of silica. H. Schulz found 0.0826 per cent. silica in the ash of man's flesh; and 0.1484 in the ash of the skin. More silica occurs in the same tissues in youth than in old age. J. E. Reynolds, arguing from several analogies between the behaviour of carbon and silicon compounds, said that it may be possible for the plant to construct from silicon compounds, ultimately derived from the soil, something akin to silicon protoplasm for use in its structures. Similar observations apply to the power of sponges to extract silica from sea-water as a part of their normal food supply and use it in cell production. He added:

All theories of life assume that its phenomena are inseparably associated with certain complex combinations of the elements carbon, nitrogen, hydrogen, and oxygen, with the occasional aid of sulphur and phosphorus. These are the elements of that protoplasm which is the physical basis of life, and by their interplay they form the unstable and complicated groupings of which that remarkable material is composed. All the phenomena we call vital are associated with the change of some protoplasm, and the oxidation of carbon and hydrogen. But it is quite open to question whether the connection of life with the elements first specified is inevitable. We can conceive the existence of similar

groupings of other analogous elements, forming other protoplasm capable of existing within much greater ranges of temp. than any plants or animals now known to us have to withstand. For example, we can imagine a high temp. protoplasm in which silicon takes the place of carbon, sulphur of oxygen, and phosphorus of nitrogen, either wholly or in part. In fact, protoplasm so far as we know it in purest form, always contains some sulphur, and often a little phosphorus, representing a very partial substitution of the kind in question.

The spectra of the sun and of different stars show the presence of silica.²³ The subject has been studied by J. N. Lockyer and co-workers, H. A. Rowland, J. Lunt, F. W. Dyson, W. M. Mitchell, W. S. Adams, O. Vogel and J. Wilsing, A. de Gramont, etc. G. Rose reported quartz in a meteorite from Xiquipulco; G. P. Merrill, in one from St. Mark's, South Africa; H. Laspeyres, in one from Toluca (Mexico); and E. Cohen, in one from Beaconsfield (Victoria). N. S. Maskelyne reported asmanite (tridymite) in a meteorite from Breitenbach. The occurrence of tridymite in meteorites has been discussed by G. vom Rath, A. Weisbach, C. Winkler, G. Tschermak, E. Mallard, E. Cohen, H. Moissan, and N. H. Winchell. The occurrence of cristobalite was reported by E. Cohen in the meteorite of Kendall Co., San Antonio, Texas. According to H. Moissan, silicon carbide (moissanite) has been found in meteorites.

§ 3. The Preparation of Silicon

The silicon prepared by J. J. Berzelius about 1808, by heating a mixture of silica, carbon, and iron was really not silicon at all, but rather an iron silicide, or ferro-silicon. H. Davy was not very successful in his attempt to reduce silica by electrolysis, or by potassium at a high temp. According to A. Dufour, there are signs that quartz is slightly reduced by hydrogen at high temp., but this reaction is not practicable as a means of preparing silicon. The reduction of silica by carbon, at the temp. of the electric arc, is, however, a satisfactory mode of preparation. Silicon appears to exist in two forms—amorphous and crystalline. According to E. Vigouroux, the difference in the two forms is a question (i) of the degree of purity rather than allotropism; and (ii) of the state of subdivision, the grain of the so-called amorphous form being much finer than the crystalline form. Purified amorphous silicon does not differ from crystalline silicon of the same degree of purity—*leurs propriétés chimiques sont identiques*. P. Lebeau came to a similar conclusion.

For a long time, on the strength of J. J. Berzelius' observations,¹ it was thought that there are two forms of amorphous silicon, the one active amorphous silicon—*vor dem Glühen*—was called *silicon- α* , and the other passive amorphous silicon—*nach dem Glühen*—or *silicon- β* . The latter was obtained by strongly heating the former, and washing the product with hydrofluoric acid. (i) The active form was combustible in air or oxygen, the passive form was incombustible in these gases; (ii) the active form was insoluble in all acids excepting hydrofluoric acid, the passive form was insoluble even in hydrofluoric acid or in a mixture of hydrofluoric and nitric acids; and (iii) the active form was soluble in an aq. soln. of potassium hydroxide, the passive form was insoluble in that menstruum. E. Vigouroux examined the products prepared according to J. J. Berzelius' directions, and concluded that the alleged modifications *ne sont pas des corps simples*, but rather impure forms of silicon; and that the observed differences are due to differences in the composition of the two forms. There are, however, differences of opinion because E. Wilke-Dörfurt showed that the amorphous silicon which is obtained by reducing silicon fluoride with sodium at a dull red heat reacts with sulphuric acid and hot water during the washing. The sulphuric acid is reduced with sulphur as one of the products. The yield of amorphous silicon by this process is therefore very small. On the other hand, the grey powder of amorphous silicon, obtained by treating with acids the metallic regulus, furnished when sodium fluosilicate is fused with sodium and aluminium, is not very active chemically, but when heated with hydrofluoric acid, it forms a brown variety of amorphous silicon which is very reactive, for it is violently attacked by conc. nitric acid, forming a white substance, possibly a nitride, which evolves ammonia when heated with sodium hydroxide. Brown amorphous silicon is transformed into the less active form when heated. If these results be confirmed, it may be necessary to reintroduce J. J. Berzelius' α - and β -amorphous silicon—*vide* Fig. 6. According to L. Cambi, the hydrolysis of black vitreous silicon sulphide, SiS, furnishes soluble silica, and amorphous silicon.

which is a paler reddish-yellow than E. Vigouroux' product. The sp. gr. is 2.08; and, after heating, its colour and properties approach those of E. Vigouroux' amorphous silicon (*vide infra*). L. Cambi regards the different varieties of amorphous silicon as indefinite masses possessing different mol. structures. L. Baraduc-Muller observed peculiarities in the thermal expansion which he attributed to the appearance of an allotropic crystalline form of silicon stable between 700° and 1025°—*vide infra*; and J. Königsberger and K. Schilling observed peculiarities in the electric resistance (*q.v.*), which they attributed to the existence of three allotropic forms of silicon.

H. St. C. Deville² claimed to have made what he considered to be a graphitic form of silicon—*graphitoid silicon*—related to the ordinary crystalline form much as graphite is related to the diamond. W. H. Miller, however, showed that both the black glistening hexagonal plates, and the dark steel-grey six-sided pyramids or needle-like crystals of crystalline or *adamantine silicon* are really octahedral crystals belonging to the same system. H. Kopp did show that the sp. ht. of ordinary crystalline silicon and of the graphitic form are different, and this conclusion was confirmed by C. Winkler. F. S. Hyde obtained silicon in graphitoid plates, by melting raw silicon, aluminium, and cryolite. By treating potassium fluosilicate with impure aluminium at a high temp., H. N. Warren claimed to have made oblique octahedral crystals of silicon different from the ordinary crystalline form. In 1904, H. Moissan and F. Siemens found that molten silver dissolves silicon, which it rejects as the metal solidifies. This form of crystalline silicon is

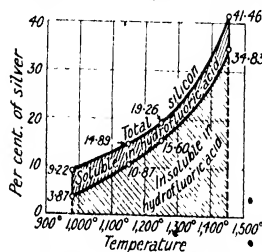

FIG. 2.—Character of Silicon crystallized from Molten Silver.

soln. of silicon in copper was investigated by W. Manchot and H. Funk. They examined the products from soln. of silicon in aluminium, silver, lead, and zinc, and concluded that queching is the essential factor in producing the soluble form; that all crystallized silicon is slowly but completely dissolved by hydrofluoric acid; and that the brown variety which resists hydrofluoric acid is in a state of passivity acquired by the occlusion of hydrogen.

The preparation of amorphous silicon.—Amorphous silicon has been made by reducing silicon halides or oxide with certain metals; by double decomposition of the silicides; and by electrolysis. J. L. Gay Lussac and L. J. Thénard³ reduced the vapour of silicon tetrafluoride by heated potassium. W. Hempel and H. von Haasy used sodium as the reducing agent, at 400°–500°: $\text{SiF}_4 + 4\text{Na} = \text{Si} + 4\text{NaF}$. The mass was allowed to cool in the current of silicon tetrafluoride so that sodium fluosilicate, Na_2SiF_6 , was formed; this was easily separated from the silicon by extraction with water. A. F. Holleman and H. J. Sluiter found that if an excess of sodium fluoride be avoided, there is practically no formation of sodium fluosilicate. When boiled with water and dil. hydrochloric acid, the residue does not, however, consist of pure amorphous silicon, for only about 40 per cent. can be volatilized in a current of chlorine, the remainder consisting principally of silicon dioxide which has been formed in the extraction of sodium fluoride. H. St. C. Deville reduced the vapour of silicon tetrachloride with heated sodium, and added:

The most prolonged washing is not sufficient to remove all the impurities; and as a result the early chemists who occupied themselves with this question—J. L. Gay Lussac and L. J. Thénard, H. Davy, etc.—were prevented from seeing the true nature of silicon.

A. F. Holleman and H. J. Slijper found that the product by this process contained 10 per cent. of silica. In a boiling soln. of benzene, sodium scarcely has any action on silicon tetrachloride.

J. J. Berzelius also reduced silicon tetrafluoride or tetrachloride with potassium, and washed the product first with cold and then with hot water. His product, called *α-silicon*—*vide supra*—was contaminated largely with hydrogen and carbon; purified by heating it in a crucible at a red heat, and washing first with hydrofluoric acid, and then with water, what he called *β-silicon* was obtained. He also obtained silicon by heating a mixture of potassium and potassium fluosilicate contained in an iron tube, and extracting the potassium fluoride by water: $K_2SiF_6 + 4K = 6KF + Si$. H. Buff and F. Wöhler heated a mixture of sodium fluosilicate with sodium covered with sodium chloride and contained in a fireclay crucible. E. Vigouroux, and W. Hempel and H. von Haasy criticized the methods of J. J. Berzelius, and H. Buff and F. Wöhler. H. Moissan said that the use of alkali metals for the reduction is very liable to give an impure product, because the action is so energetic, and the heat generated during the reduction is so great, that the vessel in which the reaction occurs is much attacked. H. N. Warren reduced silicon tetrafluoride with magnesium, and obtained amorphous silicon and magnesium silicide, but W. Hempel and H. von Haasy found the yield to be poor, and they observed a similar reaction between magnesium and silicon chloride. G. Rauber found that the reduction of silicon tetrachloride by beryllium in a sealed tube is incomplete at 270°–280°; and magnesium and zinc at 390°–400° gave only a little silicon after 64–67 hours' action; zinc dust after 28 hours' action at 280°–290° gave only a little silicon; better results were obtained with aluminium at 360°–370° after 71 hours' action. E. Lay found that molten sodium amide, $NaNH_2$, partially reduces silicon tetrachloride.

According to R. Bunsen and A. Matthiessen,⁴ sodium exerts a reducing action on silicates, glass, porcelain, etc., even at 200°, while calcium and strontium begin to act at a red heat. H. St. C. Deville reduced a mixture of silica with calcespar and potassium carbonate by means of sodium, but the resulting silicon was very impure. T. L. Phipson showed that magnesium reduces silica, and J. Parkinson obtained silicon and magnesium silicate as products of the reduction. L. Gattermann heated with a Bunsen's burner a mixture of quartz sand and magnesium contained in a test-tube, and found the main reaction corresponds with the equation: $SiO_2 + 2Mg = 2MgO + Si$. The reaction is accompanied by vivid incandescence, and if precipitated silica be used, there may be a slight explosion. If an excess of magnesium is employed, the product is mainly magnesium silicide. In any case, the product which remains after washing with hydrochloric acid is not very pure; and C. Winkler claimed a purer product by reducing silica with magnesium silicide in presence of an excess of silica, but, according to W. Hempel and H. von Haasy, the yield is very small. E. Vigouroux investigated the conditions necessary for preparing pure amorphous silicon by the reduction of silica with magnesium. If the exact amount of magnesium strictly necessary for the reduction be employed, the product is a mixture of amorphous and fused silicon, and a small quantity of magnesium silicide. If an excess of silica be used to avoid the formation of magnesium silicide, it will be very difficult to remove all the silica from the product. If magnesia be added to moderate the violence of the reaction, amorphous silicon can be obtained in a high degree of purity. If the materials are imperfectly dried, the materials may be projected from the reaction vessel with explosive violence. E. Vigouroux recommended the following procedure for making amorphous silicon:

Clear transparent quartz is powdered and intimately mixed with magnesium powder in the proportions corresponding with $SiO_2 + 2Mg = Si + 2MgO$, and with 25 per cent. of

purified commercial magnesia. Both the quartz and the magnesia should be separately calcined to drive off the moisture, otherwise a dangerous explosion may occur—particularly if precipitated silica be used instead of quartz. A convenient charge for a fireclay crucible is silica, 180 grms.; magnesium, 144 grms.; magnesia, 81 grms. The crucible and contents are placed in a furnace at a bright red heat. In two or three minutes, the reaction proceeds with vivid incandescence. The crucible is then withdrawn from the furnace and allowed to cool. The contents of the crucible are uniformly coloured maroon. The product is added to hydrochloric acid, and the insoluble residue washed by decantation. It is then treated with hydrofluoric acid, and after the vigorous action has subsided, heated to 160° . The clear liquid is decanted, and the residue again treated with hydrofluoric acid. The washed residue is then added in small portions at a time to sulphuric acid contained in a platinum dish; the mixture is heated for some hours to the b.p. of the acid so as to convert the metal fluorides into sulphates. The solid mass is washed with hot water; then with conc. hydrochloric acid, then with water, and finally heated to redness in a current of hydrogen. The product contains 96-97 per cent. of amorphous silicon. If purified silica and magnesium be employed, and the reduction be performed in a Bohemian glass tube branched with magnesia, and traversed by a current of hydrogen, a still purer product can be obtained. He obtained 99.0-99.6 per cent. silicon in this way.

E. Vigouroux found that pulverized aluminium of commerce, washed free from fatty materials by ether and alcohol, can be used in place of magnesium. The reaction commences at about 800° , and corresponds with the equation: $3\text{SiO}_2 + 4\text{Al} \rightarrow 2\text{Al}_2\text{O}_3 + 3\text{Si}$. The product with aluminium is as pure as that with magnesium, but the yield is not so good. F. E. Weston and H. R. Ellis also reduced silica with aluminium; A. Burger, with calcium; and L. Burgess, with the carbon arc.

Amorphous silicon is deposited when a cold plate is held in the flame of burning silicuretted hydrogen. According to V. Köhlschütter,⁵ silicon is separated when canal rays and disintegrated aluminium impinge on glass. H. N. Warren passed sparks through silane, and obtained a deposit of amorphous silicon on the walls of the containing vessel. A. Dufour, and H. Moissan and S. Smiles also obtained amorphous silicon by the decomposition of silicon hydrides; and O. Ruff and C. Albert, by the decomposition of silicochloroform, SiHCl_3 , at 800° . L. Cambi obtained amorphous silicon by the hydrolysis of silicon sulphide. According to W. Hempel and H. von Haasy, the silicon which separates during the cooling of soln. with less than 20 per cent. of silicon in molten aluminium, is in the amorphous state. H. N. Warren also obtained a separation of amorphous silicon from ferro-silicon; and A. E. Jordan and T. Turner found no crystals of silicon were present in iron with less than 10 per cent. of silicon, and the graphite which separates from such iron also contained no silicon. T. Naske said that silicon in excess of Fe_3Si separates when siliciferous iron is cooled. G. J. L. de Chalmont obtained amorphous brown silicon by the action of sulphur on copper silicide at 250° - 300° .

M. Junot,⁶ claimed to have obtained amorphous silicon by the electrolysis of a potassium cyanide soln. of sodium silicate, but A. J. Balard could not confirm this. H. St. C. Deville found that amorphous silicon separates at the negative electrode when a soln. of silica in a molten mixture of sodium and potassium fluorides is electrolyzed with carbon electrodes. F. Ullik obtained amorphous silicon by the electrolysis of a molten mixture of potassium fluosilicate and fluoride. According to G. Gore, a deposit of silicon is obtained when aq. soln. of alkali silicates are electrolyzed with copper electrodes. A. Minet electrolyzed a mixture of sodium chloride, cryolite, and aluminium, and obtained a silicon alloy which was not further investigated. A. Grätzel von Grätz obtained a similar alloy. H. N. Warren electrolyzed an alcoholic soln. of silicon tetrafluoride with a mercury cathode, and on evaporating the mercury from the amalgam, obtained amorphous silicon.

The preparation of crystallized silicon.—In 1854, H. St. C. Deville⁷ accidentally prepared a lustrous mass of plates of silicon by electrolyzing a double chloride of aluminium and sodium which contained siliceous impurities. The aluminium was removed by hydrochloric acid. He said:

This body possesses *une inaltérabilité encore plus grande*; and has all the chemical properties which J. J. Berzelius attributed to the residue obtained by the incomplete combustion of ordinary silicon. Thus, in order to give an idea of the inalterability of the

action of the most energetic reagents, I may say that the new silicon has been heated white hot in a current of pure oxygen without changing in weight.

He also pointed out that the electrolysis of all siliceous materials in fused alkali fluorides furnishes silicon. F. Wöhler obtained a globule of aluminium by fusing sodium and cryolite in a fireclay crucible, and when the aluminium was removed by acid, crystalline silicon remained. The element is nearly always obtained in the crystalline form when a compound of silicon is reduced by magnesium, zinc, or aluminium in the presence of other metals; and, according to J. Robbins, silver and tin behave similarly. H. N. Warren obtained silicon crystals by melting silicon with an aluminium alloy containing 10 per cent. of tin; and W. Hempel and H. von Haesly said that silicon separates in the crystalline form from aluminium containing over 20 per cent. silicon. E. Eggertz found crystals of silicon in many kinds of iron. H. Hanemann studied the formation of silicon when carboniferous iron is heated in contact with fireclay crucibles. L. Troest and P. Hautefeuille found that when amorphous silicon is fused and allowed to cool, crystalline silicon is formed. In H. St. C. Deville and H. Caron's process, potassium fluosilicate was reduced by sodium in the presence of zinc; and F. Wöhler used a mixture of aluminium and potassium fluosilicate. In either case, the zinc or aluminium can be removed by treating the alloy with acids. F. Wöhler's process is as follows:

A mixture of 125 grms. of aluminium and 400 grms. of potassium fluosilicate, K_2SiF_6 , is heated in an iron crucible. The reaction proceeds tranquilly. After half an hour's heating to about 1400° , the crucible is removed and allowed to cool. The crucible is broken. The metallic button covered by a thin layer of scoria and weighing about 110 grms. is dislodged from the bottom of the crucible. The button has a silvery colour, is very brittle, and has a very crystalline texture. The button is digested in hydrochloric acid, and then boiled in nitric acid; it is finally treated with hydrofluoric acid, washed, and dried. About 50 grms. of crystalline silicon are obtained.

A. J. Kieser analyzed a sample of silicon prepared by F. Wöhler's process, and found 71.81 per cent. of silicon; 0.33 per cent. of silica; 2.51 per cent. of iron; and 25.32 per cent. of aluminium. C. Winkler heated to redness for about 45 mins. a mixture of cryolite, powdered quartz, and aluminium powder, all covered with a layer of sodium chloride. T. Scheerer emphasized the difficulty of removing aluminium from silicon prepared in this manner. L. Weiss and T. Engelhardt recommended reducing potassium fluosilicate with massive aluminium, a better regulus being obtained than when aluminium powder is used. The regulus is crushed and extracted successively with hydrochloric, conc. sulphuric, and hydrofluoric acids. The product, even after repeated boiling in a state of fine powder with hydrofluoric acid, contains 0.3-0.5 per cent. Fe, 0.1 per cent. Cu, and 0.72 per cent. SiO_2 .

H. St. C. Deville obtained fine needles of silicon by heating aluminium to redness in the vapour of silicon chloride; when silicon fluoride was used, the product always contained aluminium fluoride. H. St. C. Deville found that if aluminium be heated to a high temp. in contact with glass or quartz, the metal always retains some silicon. E. Vigouroux made silicon by heating quartz powder mixed with an excess of aluminium in a carbon crucible in an electric furnace, and obtained silicon with a fine crystalline fracture. The reaction proceeds at a lower temp. in the presence of a flux, and he preferred a mixture of 120 grms. of aluminium, 30 grms. of quartz, and 220 grms. of potassium fluosilicate. A. J. Kieser used a similar process, and obtained silicon with 0.1887 per cent. of alumina. K. A. Kühne used the thermite process with a mixture of 360 parts of silica, and 400 parts of aluminium; he also used a mixture of silica, 36 parts; aluminium, 40 parts; and sulphur, 50 parts in a fireclay crucible. A. F. Holleman and H. J. Slijper used a modification of this process. O. P. Watts recommended using cryolite or felspar as a flux; K. Gröppel, a basic aluminium silicate. W. G. Mixer recommended purifying the silicon by recrystallization from molten aluminium and subsequent treatment with hydrofluoric acid, potassium pyrosulphate, and hot purified sulphuric acid.

E. H. and A. H. Cowles and C. F. Mabery⁸ made silicon alloys by reducing silica with carbon in the electric furnace, and H. Moissan made crystalline silicon by reducing silica in a similar way. H. Moissan said:

When an intimate mixture of carbon and powdered rock crystal is heated in a carbon cylinder closed at one end in an electric furnace, the orifice of the tube is soon covered with snow-like flakes of silica; lower down are found beautiful crystals of silicon carbide; lower still are rings of brilliant black crystals interspersed with globules which have been fused. Neither the crystals nor the globules are attacked by a mixture of nitric and hydrofluoric acids. They inflame in fluorine gas forming silicon fluoride. Some of the crystals resemble those obtained by the soln. of silicon in molten zinc. The crystalline dust which collects in the tube contains 28-30 per cent. of crystalline silicon.

K. Gröppel obtained silicon by heating aluminium silicates, silica, and carbon in the electric arc furnace. The final slag had the composition $\text{SiO}_2 + 6-7\text{Al}_2\text{O}_3$. About 3 per cent. of cryolite renders the slag sufficiently fluid. O. P. Watts found that sodium silicate gives better results as a source of silicon than does silica, glass, or calcium silicate; he also obtained silicon by reducing silica or silicates with silicon carbide. The reduction of silica by carbon or silicon carbide in the electric furnace has been discussed by G. J. L. de Chalmot, R. Scheid, F. J. Tone, etc. J. Königsberger and K. Schilling electrolyzed silica with carbon electrodes at about 3600° , and the product contained 0.1 per cent. of silica, and less than 0.01 per cent. of carbon.

A. Lampen found that carborundum breaks up into silicon and graphite between 2200° and 2240° ; and W. R. Hodgkinson and F. K. Lowndes, that if a platinum wire be heated white hot in thoroughly dried silicon tetrafluoride, crystalline silicon is formed. J. N. Pring and W. Fielding also obtained small hard crystals when a silicon tetrachloride in the presence of hydrogen is decomposed by a carbon rod heated electrically to about 1700° . Some silicon carbide is formed at the same time; at 1925° , the whole of the deposit was silicon carbide.

E. W. von Siemens and J. G. Halske⁹ found that silicon films or silicon-mirrors could be obtained by placing the surface to be plated in a uniformly heated pipe above the temp. of decomposition of silicon hydride, and passed through the system a current of that gas mixed with hydrogen. The mirror so produced is used in work with ultra-violet rays.

H. Kuzel¹⁰ prepared colloidal silicon suspended in water or other liquid, and the process was also used for colloids of elements of high m.p. such as chromium, manganese, molybdenum, uranium, tungsten, vanadium, tantalum, niobium, titanium, boron, thorium, zirconium, platinum, osmium, and iridium. The element is first brought to a fine state of division by grinding and sifting, or by cathodic disintegration, and is then converted into the colloidal state by repeated alternate treatments for long periods with dil. acid soln. and dil. alkaline or neutral soln. under the influence of moderate heat and violent agitation. After each treatment the material is washed with distilled water, or other solvent until completely free from the reagent employed. H. Kuzel also showed that gels of these elements are peptonized—or reconverted into colloidal soln.—by digestion with ammonia or amines or with very dil. soln. of alkali hydroxides or carbonates. The peptonized soln. have a powerful agglomerating action on powdered metals.

According to F. Limmer,¹¹ the amorphous silicon of commerce contains 20-65 per cent. of crystalline silicon, 2-12 per cent. of silica. B. Neumann found commercial silicon prepared in the electric furnace contained 70-97.5 per cent. of silicon; and a minimum of 2.5 per cent. impurities—0.1-3.5 per cent. iron; 0.14-0.70 per cent. aluminium as metal or carbide; 0.22-1.40 per cent. of calcium; and 1.9-24.0 per cent. of insoluble matters, chiefly ferrosilicon, silica, and silicon carbide. P. F. Spielmann reported that commercial graphitic silicon contained:

Silicon	Iron	Aluminium	Silica	Alumina
93.91	2.75	0.41	2.65	0.46 per cent

The preparation of silicon of a high degree of purity has not been successful, and in many cases where the properties have been determined, the (undetermined) degree of purity has been very low. It is therefore probable that statements of some of the properties of silicon will be found erroneous, though they may be right for the impure element. Contradictory statements also appear.

§ 4. The Physical Properties of Silicon

According to J. J. Berzelius,¹ the colour of the so-called amorphous silicon is dark brown, and the tint is darker after calcination than before. Crystalline silicon *en masse* is dark steel-grey, with a reddish tinge in reflected light. Small crystals are often transparent and light orange in colour. When it occurs in almost black six-sided plates with a metallic lustre resembling graphite, it is called *graphitoidal silicon*; F. S. Hyde said that the crystals appear to be incomplete octahedra. The *adamantine silicon* appears in steel-grey needle-like crystals, or in hexagonal prisms; when prepared by the zinc process, silicon seems to favour the octahedral habit, and when made by the aluminium process, the crystals are lamellar. The

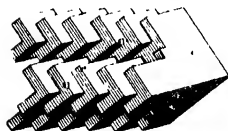

FIG. 3.—Pile of Octahedral Crystals of Silicon.

habit is probably largely affected by the rate of cooling. H. de Sénarmont found that the tabular and acicular crystals prepared by H. St. C. Deville were octahedral and sometimes arranged in series (Fig. 3); and often with truncated and trihedral apices. According to W. H. Miller, both the graphitoidal and adamantite crystals are octahedral. They belong to the cubic system. According to P. Groth, the crystals of silicon and carbon are not isomorphous. Although carbon and silicon unite to form a carbide, they do not to mixed crystals, and silicon carbide itself is dissimilar in crystalline form from either of its components. Carbon tetraiodide and silicon tetraiodide crystallize in the cubic system, but further information as to the isomorphism of the two compounds is lacking. As G. Jerusalem has emphasized, no instance is on record in which silicon replaces carbon without a profound modification of the crystalline form. Isomorphism might be expected between the metal carbonates and metasilicates, but none has been observed—e.g. lithium carbonate, LiCO_3 , is monoclinic, lithium metasilicate, LiSiO_3 , is rhombohedral; nor has any isomorphism been observed between the carbonates and metasilicates or metatitanates of the bivalent metals— CaSiO_3 , $(\text{Mg}, \text{Ca})\text{SiO}_3$, MgSiO_3 , MnSiO_3 , MgTiO_3 , and FeTiO_3 . According to J. Königsberger, the crystals of silicon may be isomorphous with those of titanium and zirconium.

According to A. W. Hull, P. Debye and T. Scheerer, W. Gerlach, K. C. Bain, W. L. Bragg, L. W. McKeehan, and* H. Küstner and H. Remy, the space-lattice deduced from the **X-radiograms** is identical with that of the diamond. There are two intermeshed face-centred lattices, one being displaced with reference to the other along a cube-diagonal, a distance of one-fourth the length of the diagonal. The side of the cube is 5.42 Å. to 5.43 Å., compared with 3.56 Å. for the diamond, and the distance between adjacent atoms is 2.35 Å. compared with 1.54 Å. for the diamond. There are 8 atoms per unit cube. R. N. Pease calculated 1.17 Å. for the atomic radii of the atoms in silicon; and W. L. Bragg, and M. L. Huggins, 1.17 Å. A. L. Norbury studied the at. vol. of silicon in alloys. P. Debye found no difference in the X-radiograms of amorphous and crystalline silicon, showing that the two forms are structurally the same. M. L. Huggins, L. A. Turner, and H. Collins discussed the electronic structure of the silicon molecule—*vide silica*. H. Moissan and F. Siemens' soluble silica forms yellow translucent plates rather darker in colour than ordinary crystalline silica. H. N. Warren's form was octahedral like ordinary crystalline silica. According to C. Winkler, the crystals are very hard; they scratch glass but not topaz. J. R. Rydberg places their hardness at about 7 when that of the diamond is 10.

F. Wöhler gave 2.490–2.493 for the **specific gravity** of graphitoid silicon at 10°; A. Harmening gave 2.493; C. Winkler, 2.004–2.197 for specimens obtained from molten zinc; W. H. Miller, 2.337; H. St. C. Deville, 2.493; and K. Honda, 2.399. L. Playfair gave 2.48 as the mean of six determinations of the sp. gr. of adamantine silicon. L. Weiss and T. Engelhardt obtained 2.3013 at 19° as the mean of five determinations of a sample with 1.58 per cent. aluminium, and 97.46 per cent. silicon; and 2.3454 at 19° as the mean of six determinations for samples of silicon with rather less aluminium. The sp. gr. of a sample of amorphous silicon made by E. Vigouroux' process was 2.35 at 15°, and that of the crystalline form a little smaller. L. Cambi gave 2.08 for the sp. gr. of a sample of the amorphous element made by the hydrolysis of silicon sulphide. The different amorphous forms, said he, are not clearly-defined allotropes. H. Moissan and F. Siemens gave 2.30–2.42 for the sp. gr. of crystalline silicon soluble in hydrofluoric acid. P. P. Spielmann gave 1.90 for the sp. gr. of commercial silicon. The **atomic volume** of silicon is 11.4, if the sp. gr. be taken as 2.42. T. W. Richards found the mean change of vol. per 0.987 atm. press. between 98.7 and 5×98.7 atm. press. is 0.16. C. A. Edwards found the **hardness** of silicon on Brinell's scale to be 240; and C. A. Edwards and A. M. Herbert gave 89.3 for the **plasticity** number when that of platinum is 116. The coeff. of **compressibility** is 0.32×10^{-6} at 20° between 100 and 500 megabars when the compressibility of mercury is 3.95×10^{-6} . E. Grüneisen showed that if α be the coeff. of linear expansion; v the vol. of a gram-atom; and β , the coeff. of compressibility, then $\alpha v/\beta$ is nearly constant for most of the metals, and for silicon. J. H. Hildebrand and co-workers calculated relative values for the **internal pressure** of silicon and other elements.

According to H. Fizeau,² the coeff. of **thermal expansion** is $\alpha = 0.00000763$ per degree at 40°, and 0.00000780 at 50°. This makes the coeff. of cubical expansion $3\alpha = 0.000023$. According to L. Baraduc-Muller, the mean value of the coeff. between 15° and 1000° is $\alpha = 0.00003468$; it is fairly constant between 200° and 700°; it increases rapidly to 805°, decreases to its original value at 835°, again increases slightly to 900° and then becomes small and negative at 970°; it increases and becomes positive at 1000°, and increases slightly up to 1055°. The value of $da/dt \times 10^4$ from 607°–700° is 5.05; 700°–805°, 10.47; 805°–835°, 4.30; 835°–900°, 2.30; 900°–970°, –0.85; 970°–1000°, 2.66; 1000°–1025°, 2.80; 1025°–1055°, 3.31. S. Valentiner and J. Wallot found that the coeff. of expansion decreases with a falling temp., becomes zero at –157°, and is negative at liquid air temp. H. V. Regnault³ obtained numbers for the **specific heat** of crystalline silicon varying from 0.1673 to 0.1784; and for that of fused silicon, from 0.1557 to 0.1750 between about 12° and 100°. H. Kopp gave 0.165 for the sp. ht. of crystalline

silicon, 0.138 for fused silicon, 0.181 for graphitoid silicon, and 0.214 for amorphous silicon between 20° and 50°. H. F. Weber gave 0.1964 for the sp. ht. of crystalline silicon at 128.7°, and 0.2029 at 232.4° (vide I, 13, 12). A Wigand obtained 0.1712 for grey microcrystalline silicon between 0° and 99°. T. W. Richards and F. G. Jackson obtained 0.118 between -188° and 20°; A. S. Russell obtained 0.0861 at -135° for crystalline silicon, and for amorphous silicon, 0.0913 at -135°, and 0.1796 at 27°. C. Forch and P. Nordmeyer found the sp. ht. to increase with rise of temp. Thus:

	-184°	-39.07°	43.13°	71.07°	100.00°	212°	252.03°
Sp. ht.	0.0876	0.1360	0.1697	0.1833	0.1901	0.2011	0.2029

P. Nordmeyer and A. L. Bernoulli gave 0.1234 between -185° and 20°. H. Schimpff represented the sp. ht., c , of 99.2 per cent. silicon at the temp. θ° , by $c = 0.165428(\theta - 17) + 0.01584210(\theta - 17)^2 - 0.003742(\theta - 17)^3$; he gave 0.1597 for the true sp. ht. at 0°, and 4.54 for the atomic heat at 0°. H. F. Weber gave 5.75 for the at. ht. at 100°. The deviation of the at. ht. from Dulong and Petit's law has been discussed I, 13, 12. The at. hts. computed from the results of W. Nernst and F. Schweser below -183.2°; H. Schimpff, between -150° and 0°; and by H. F. Weber between 21.6°, and 232.4° are as follows—the temp. being taken on the absolute scale:

	20.1°	33.7°	53.7°	89.8°	173°	273°	323°	359°	505.4°
At. ht.	0.031	0.152	0.548	1.524	3.21	4.54	4.96	5.38	5.74

The results are plotted in Fig. 3 in connection with carborundum. The at. ht. was also considered by F. Michaud, and E. van Aubel. A. Magnus represented the thermal capacity of silicon between 0° and θ° by $Q = 0.1723\theta + 6.40 \times 10^{-6}\theta^2 - 2.575 \times 10^{-8}\theta^3$. E. D. Eastman gave for the entropy of silicon 5.7 cal. per degree at 25°; and G. N. Lewis and co-workers, 4.7 cal. per degree. The thermal conductivity, 0.20 cal. per cm. per second per degree, was measured by J. Königsberger and J. Weiss.

According to C. Winkler,⁴ silicon can be heated to redness without changing its sp. gr., or losing perceptibly in weight. Both H. N. Warren, and F. S. Kyde said that graphitic silicon is infusible before the blowpipe. C. M. Despretz melted this element, but his observations were made with the impure product obtained by the earlier workers. H. St. C. Deville said that it can be melted in a good wind furnace—*feu de vent*—and he estimated that its melting point lies between m.p. of cast iron and steel—say between 1400° and 1500°—and he showed that the molten element can be cast without perceptible oxidation. H. Moissan found that silicon can be readily melted in the electric furnace, and that the molten element is bluish or steel-grey. H. Moissan and F. Siemens said that the m.p. is near 1500°. T. W. Richards gave 1460° for the m.p. G. Arrivant gave 1415°; R. Vogel, 1408°; W. Fränkel, 1412°; H. Giebelhausen, 1425°; R. S. Williams, 1414°; W. R. Mott, 1430°; F. Dörinkel, 1458°; W. Guertler and G. Tammann, 1425°; and K. Lewkonja, 1443°. According to W. Fränkel, molten silicon, like bismuth, expands on solidification.

P. Schützenberger and A. Colson stated that the volatility of silicon is not appreciable in the blast furnace, but they found that platinum-foil heated to a reddish-white heat amidst a mass of lampblack contained silicon which presumably was carried as vapour through the lampblack from the crucible. H. Moissan believes that the conclusion is a *non sequitur*, for the vap. of silicon would have been arrested by the carbon. L. Troost and P. Hautefeuille said that silicon appears to be volatile when melted in a stream of hydrogen carrying some silicon tetrafluoride or tetrachloride. This apparent volatilization is attributed to the formation of lower chlorides or fluorides which are stable at a low temp. and at a red heat, but undergo dissociation at intermediate temp. The reaction was discussed by P. Duhem—vide hexachlorodisilane. A. Ditte showed that

selenium and tellurium hydrides exhibit a similar phenomenon; C. W. Hasenbach also observed a similar effect with nitrogen trioxide; and H. Debray and A. Joly, with ruthenium oxide. P. Hautefeuille and A. Perrey found that when the vap. of aluminium chloride is passed over aluminium heated at 440° in a glass tube, a deposit is formed of an amorphous substance, which consists mainly of silicon mixed with small quantities of iron and aluminium. It would seem, therefore, that aluminium is retained by silicon heated at 1300°, but is given up when the metal is heated at a temp. much below its softening point. C. Friedel also observed that silicon is volatilized in the electric arc between silicon poles—vide iron silicides. A. Dufour noted that the passage of an electric discharge through a vacuum tube filled with silicon hydride immediately causes a deposit of amorphous silicon; if, however, the current is continued for about an hour, the original deposit of silicon gradually disappears and is re-formed in the dark space round the cathode. The final deposit is always formed in the dark space, even if other parts of the tube are cooled to 80°; hence the phenomenon cannot be due to the distillation of the silicon from the hot regions to the colder. The facts can only be explained satisfactorily by supposing the silicon to recombine with the hydrogen present to form silicon hydride, which is decomposed in the dark space by the impact of the corpuscles, emitted from the cathode. H. Moissan found that silicon can be distilled in the electric arc furnace, and that the vap. condenses as small globules in the cold part of the tube; E. Vigouroux observed that the vapour condensed in the form of lamellar crystals. W. R. Mott gave 1800° for the boiling point; and E. Tiede and E. Birnbrauer, 1350°. According to H. von Wartenberg, the vap. is polyatomic, and the latent heat of vaporization of silicon is -44,000 cal. per gram-atom for temp. up to 1315°. The conc. of silicon vap. over crystalline silicon when the partial press. of hydrogen is one atm. is 1.15×10^{-3} at 1205°, and 3.00×10^{-3} at 1315°. J. J. van Laar calculated 4920° for the critical temperature; and 1450 atm. for the critical pressure. Assuming that the allotropic change from amorphous to crystalline silicon is a real phenomenon, L. Troost and P. Hautefeuille state that the heat of transition: $\text{Si}_{\text{amorphous}} \rightarrow \text{Si}_{\text{crystalline}} + 8.059$ Cals., but H. von Wartenberg believes this value to be much too high, and estimates that the heat of transition is less than 2 Cals. The heat of combustion of amorphous silicon was found by H. von Wartenberg to be 195 Cals.; M. Berthelot gave 184.5 Cals., and W. G. Mixer, $\text{Si} + \text{O}_2 = \text{SiO}_2 + 191$ Cals.

H. von Wartenberg⁵ gave 3.87 for the refractive index, μ , of silicon; and for the absorption coeff., $\mu k = 0.47$. J. H. Gladstone, A. Haagen, A. Schrauf, and J. Kannonikoff computed the refraction equivalent—the product of the at. wt., and $(\mu - 1)D$, where D is the sp. gr.—and found values varying from 6.0 to 11.25, showing, as G. Abati emphasized, that the refraction eq. depends on the constitution of the compound in which the element occurs. A. Schrauf, and A. Haagen found that the molecular rotatory power, calculated from that of quartz, is 0.27. H. von Wartenberg gave 35.7 per cent. for the reflecting power of silicon; and W. W. Coblentz found that the reflecting power of polished silicon is greatest for light rays in the blue part of the spectrum, and falls away rapidly towards the ultra-red. The curves for the percentage amount of light of wave-length λ ($\mu = 0.001$ mm.), reflected from two samples of polished commercial silicon, are illustrated in Fig. 4. The curves remained horizontal as far as they were examined, viz. to $\lambda = 10\mu$. E. P. Lewis and A. C. Hardy found the reflective power of silicon for rays below $\theta = 1860$ to be 25–44 (rock salt, 8–9); I. C. Gardner also measured the reflection coeff. of the extreme ultra-violet rays.

The spectrum of silicon has not yet been made clear. The lines are very numerous, and they occur principally in the ultra-violet. Different bands and lines

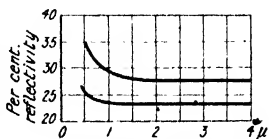

FIG. 4.—Reflecting Power of Silicon.

are obtained under different conditions, and it is not always clear which are due to silicon and which to compounds of silicon with oxygen, hydrogen, or the halogens. J. Plücker⁶ obtained the **spark spectrum** by passing the electric discharge through silicon tetrachloride in a vacuum tube, and other observations on the line spectrum have been made by G. Kirchhoff, J. M. Séguin, A. Mitscherlich, L. Troost and P. Hautefeuille, G. Salet, A. del Campo and co-workers, R. A. Sawyer and R. F. Paton, G. Ciamician, H. A. Rowland, J. M. Eder and E. Valenta, E. Demarcay, J. N. Lockyer and co-workers, A. de Gramont, J. Lunt, W. N. Hartley, K. von Wesendonck, J. Hartmann, F. Exner and E. Haschek, E. B. Frost and J. A. Brown, W. Crookes, G. Städler, A. Hagenbach and H. Konen, W. M. Mitchell, A. Dufour, J. H. Pollok and A. G. G. Leonard, F. W. Dyson, W. S. Adams, C. Fabry and H. Buisson, E. Goldstein, C. Porlezza, etc. G. Salet gave for the most prominent lines in the visible spectrum: 6366, 6341, 5981, 5960, and 5948 in the orange-yellow; 5772 in the yellow; 5708 and 5646 in the yellowish-green; 5057 and 5041 in the green; and 4131, 4126, and 4103 in the violet—vide Fig. 5. In the ultra-violet the chief lines, according to C. Porlezza, and

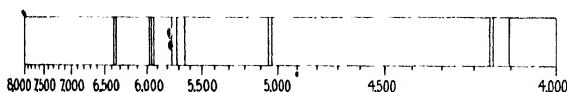

FIG. 5.—Spark Spectrum of Silicon.

J. C. McLennan and E. Edwards, are 2881.73, 2528.60, and 2516.26. The **flame spectrum** of silicon in the oxyhydrogen flame was found by W. Huggins to be continuous. G. Salet observed some bands in the spectrum of the hydrogen flame charged with silicon halides. The chief lines in the spectra of silicon chloride, bromide, and iodide are the same. The flame spectrum has also been studied by A. de Gramont and C. de Watteville. The **arc spectrum** has been observed by J. Hartmann and G. Eberhard, C. Porlezza, F. Exner and E. Haschek, etc. The most intense lines in the ultra-violet arc spectrum are, according to C. Porlezza, and J. C. McLennan and E. Edwards, 3905.70, 2881.70, 2528.60, 2524.22, 2516.20, and 2507.01. G. D. LaVeing and J. Dewar, W. N. Hartley, F. Exner and E. Haschek, J. C. McLennan and co-workers, R. A. Millikan and I. S. Bowen, etc., studied the **ultra-violet spectrum**. J. N. Lockyer showed that successive spectra are developed by silicon as the energy of excitation is increased. What he called Si^{arc} corresponded with the arc spectrum; Si^{v} with the spark spectrum which is associated with some doublets; Si^{w} is associated with some triplets; and Si^{p} is associated with a pair of lines in the violet. A. Fowler, in 1914, showed that the enhanced lines of the alkaline earth metals furnished series similar to the arc lines except that the series constant was four times its normal value. According to the electron theory, this means that the enhanced lines are produced by atoms which have lost one electron, and hence it was inferred that atoms which have lost one electron will give a series with $4N$ in place of the normal Rydberg's constant N . This is the case with the series in the spark spectrum of silicon which has the constant $4N$ corresponding with Si^+ . The triplets in series III seem to be associated with Si^{++} , and the IV-silicon series has a constant of $16N$, which is taken to indicate the existence of radiating atoms which have lost three electrons, Si^{+++} . The regularities in the band spectrum were studied by C. Porlezza, W. Jevons, H. Deslandres, R. B. Lindsay, and W. Jevons. A. de Gramont discussed the sensitiveness of the spectrum of silicon in steels. W. J. Humphreys studied the effect of *pressure* on the spectrum of silicon; and J. Chautard, A. Cotton, G. Gerndt, H. M. Reese, P. Zonta, A. Dufour, etc., the effect of a *magnetic field*. The sensitiveness of the silicon spectrum for analytical work has been investigated by A. de Gramont. The sensitiveness with soln. of water-glass is such that with a dilution of 1 : 10,000, six silicon lines between 2578.60 and 2507.01 and the lines 2881.70 can be detected.

F. Haber⁷ computed the vibration frequency of silicon for the red ray to be 13.57×10^{12} , and for the violet ray, 3.69×10^{13} . J. E. P. Wagstaff gave $\gamma = 9.6 \times 10^{12}$. E. H. Kurth examined the X-rays from silicon. J. C. McLennan and M. L. Clark gave 149.5 for the critical voltage of the L-series of X-rays from silicon; and A. E. Lindh studied the K-series. J. Ewles found the minimum voltage for the excitation of the whitish-yellow cathodoluminescence of amorphous silicon to be 1600, and for the red cathodoluminescence of crystalline silicon 2400. H. S. Roberts and L. S. Adams studied the crystal of silicon as a radio-detector.

J. J. Berzelius⁸ said that "amorphous silicon does not conduct electricity, but this property cannot be regarded as being at variance with the supposed metallic nature of silicon, for this element has hitherto been obtained only in a state of minute subdivision, and finely divided iron, obtained by igniting ferrous oxalate, is likewise non-conducting." H. St. C. Deville said that the electrical conductivity of crystalline silicon is like that of graphite. A. C. Becquerel said that fused or crystalline silicon is a very poor conductor, and in consequence it becomes hot when conducting a current. F. le Roy utilized this property to make an electrically heated furnace with agglomerated rods of silicon as the resistance medium. The electrical resistance of a rod 40 sq. mm. in cross-section and 10 cms. long was 200×10^6 micro-ohms under conditions where a similar rod of carbon had a resistance of 150×10^3 micro-ohms, and a similar rod of nickel-brass had a resistance 850 micro-ohms. The temp. coeff. of the resistance is negative, and it is 40 per cent. less at 800° than it is at 0°.

F. Streitz attributed the negative temp. coeff. of the resistance of silicon to the presence of minute cavities which close as the temp. rises. According to J. Königsberger and K. Schilling, the absolute electrical resistance per c.c. falls from 0.290 at -189° to 0.0385 at 217° (Fig. 6); it then abruptly rises to 0.162, and falls to 0.85 at 435° ; and again rises abruptly to 0.100, and falls to 0.022 at 835° .

It is assumed that these changes correspond with the conversion of what they call α -silicon to β -silicon between 210° and 217° ; and with the conversion of β -silicon to γ -silicon between 435° and 440° . Both changes are reversible. The electrical conductivity of silicon is thus an exception to the general rule that the modification most stable at the higher temp. has the smallest electrical resistance. F. Fischer and E. Baerwind found the sp. gr., and the thermoelectric power of the supposed modifications are independent of the rate of cooling and are not, therefore, likely to belong to allotropes. The negative variety can be converted into the positive form by fusion in a vacuum cathode furnace, and it is not therefore an effect of aluminium. The negative variety is supposed to be a solid soln. of a small quantity of the oxide in silicon. J. Königsberger and J. Weiss gave 12.5×10^{-9} ohms for the sp. resistance of silicon at 30° . E. Thomson made some observations on this subject. K. Höjendahl examined the theory of the conductivity of silicon based on the electronic theory. P. W. Bridgman found the resistance of silicon decreases under press., but the press. coeff. becomes less the higher the press. At 0° , the total decrease under a press. of 12,000 kgms. per sq. cm. was 14.0 per cent., and at 52° , 15.8 per cent.; another sample gave 10.1 per cent. at 0° and 15.3 per cent. at 95° . The average temp. coeff. of one sample was $+0.000117$ between 0° and 52° ; and of another $+0.000615$ between 0° and 95° . The temp. coeff. is much more susceptible to impurities than the press. coeff. He estimates that for pure silicon the press. coeff. of the resistance will be of the order -0.000012 when the press. is expressed in kgms. per sq. cm. This coeff. is high, being nearly

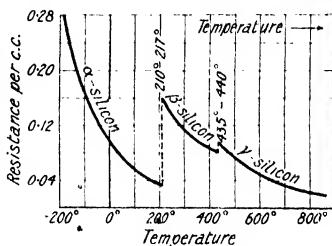

FIG. 6.—The Effect of Temperature on the Electrical Resistance of Silicon.

the same as that of lead. The use of silicon as a crystal detector in wireless telephony—*vide* carborundum, 5, 39, 18, has been discussed by R. C. Hartsough,⁹ L. S. McDowell and F. G. Wick, and F. Fischer and E. Baerwind.

A. Iljef¹⁰ found the Thomson effect at 0° and 100° to be negative; J. Königsberger and J. Weiss found the thermoelectric force of silicon against copper to be 478×10^{-6} volt per degree. C. Benedicks found for copper against silicon 608 microvolts, the largest value so far discovered. For F. G. Wick's observations on the silicon-lead couple, *vide* lead. The General Electric Co. patented the Cu-Si thermocouple for pyrometric work; it gave 415 microvolts per degree. F. Fischer and co-workers found that some specimens of silicon are positive to copper, and others as strongly negative, and a thermocouple composed of the two varieties may have a thermoelectromotive force as high as 820 microvolts per 1°. The two varieties do not differ characteristically in electrical conductivity; but the difference is due to the presence of silica. Melting silicon in contact with magnesia, lime, or alumina renders it positive, silica being removed. On the other hand, melting silicon so that a part of it burns and the oxide thus formed dissolves, renders it negative. According to K. Honda, the sp. magnetic susceptibility at 18° is -0.123×10^{-6} mass units for a sample of crystalline silicon containing 0.200 per cent. of iron as impurity; and -0.143×10^{-6} for a sample with 0.085 per cent. of iron. These constants were not affected by variations of temp. S. Meyer gave $+0.01 \times 10^{-6}$ at 16°, and for another sample $+0.2 \times 10^{-6}$. A. Duvalier, and B. Cabrera studied the relation between the magnetic properties and the electronic structure of the silicon atom.

§ 5. The Chemical Properties of Silicon

Silicon, carbon, and boron form a small group of elements which exhibit allotropism, presumably owing to high mol. complexity. This is evident by the low volatility of these elements even at high temp., and by their low chemical activity towards reagents generally. Silicon is feebly electronegative, and has a greater tendency to form compounds with the non-metals than with the metals. Silicon lies next to carbon in the fourth group of elements in the periodic table, but the relationship to carbon is not very close. Silicon behaves as a quadrivalent element, although there are a few cases in which it appears to be bivalent: *vide infra*. According to E. Vigouroux,¹ and E. Wilke-Dörfurt, as previously stated the difference between the so-called amorphous and crystalline silicon is due to the finer state of subdivision of the former. In consequence, the former appears to be more chemically active, but a similar state of activity can be obtained by the mechanical comminution of crystalline silicon. H. Moissan and S. Smiles made a silicon of great reactivity by passing sparks through liquefied silicon hydride. The product, for example, reduces a soln. of cupric sulphate slowly at ordinary temp., and rapidly when boiling; at 50°-60°, it reduces a soln. of mercuric chloride to mercurous chloride; and it reduces a boiling soln. of a gold salt. These reactions are not given by silicon prepared in the ordinary way. X-radiograms of amorphous and crystalline silicon show no difference in structure. The greater reactivity of the pseudo-amorphous form is due to its extremely finely divided state. According to W. Manchot, when rubbed with lead dioxide, the pseudo-amorphous form takes fire, the crystalline form gives no reaction.

According to E. Vigouroux, amorphous silicon readily absorbs hydrogen and many other gases, including water-vapour, from which it can be freed only by heating to redness. Both amorphous and crystalline silicon were found by E. Vigouroux, and A. Dufour to react with hydrogen at a high temp., although C. Friedel had previously failed to obtain a positive result at the temp. of the electric arc. J. J. Berzelius said the silicon- α which he made burns with a vivid flame when slightly heated in air; only about one-third of the silicon is burnt, however, since the remainder is protected from the air by the silica formed; about two-fifths is burnt under similar conditions in oxygen. On the other hand, the silicon- β

can be heated white hot before the blowpipe without taking fire. From the evidence, it appears as if the former were really an alloy of potassium and silicon, and that the potassium had been expelled from the latter by ignition in a closed vessel. In either case, probably much silica was also present. J. J. Berzelius continued that silicon which has been rendered coherent by gradual exposure to a white heat does not take fire at a red heat in air or in oxygen. W. Hempel and H. von Haasy observed no oxidation in air at 150°. G. Tammann said that he observed no increase in weight after heating crystalline silicon in air for 10 mins.; but after 5 mins. at 1100°, there was a 3 per cent. increase in weight. H. St. C. Deville, and F. Wöhler said that crystalline silicon can be heated to whiteness in oxygen without change. This is not quite right. According to E. Vigouroux, silicon is not changed in warm air, but it is attacked superficially when heated to 400° in oxygen. L. Weiss and T. Engelhardt said that silicon is not oxidized by oxygen at 700°. N. B. Pilling and R. E. Bedworth investigated the oxidation of silicon. E. Vigouroux found that silicon burns in oxygen provided the temp. be raised to the ignition point very quickly before a protective crust of silica has had time to form. In order to do this, there should be a rapid current of dry oxygen, and the silicon finely divided. If the powder be projected into a red-hot crucible, each grain scintillates for a moment, and this also occurs when the powder is passed through Bunsen's flame. This incandescence is due to an incomplete, superficial combustion. The surfaces of the grains become white, and the silica can be removed by washing with hydrofluoric acid. L. Weiss and T. Engelhardt found that water at ordinary temp. is decomposed by finely divided silicon; and E. Wilke-Dörfurt observed that silicon is oxidized by water boiling under a reflux condenser, and in an atm. of carbon dioxide. H. Moissan and F. Siemens said that amorphous silicon does not decompose water in a platinum vessel, but in a glass vessel, at 95°, an appreciable decomposition occurs in 6-12 hrs. This is due to the presence of alkali dissolved from the glass, and the action occurs in a platinum vessel if the water contains a trace of alkali. E. Vigouroux found that at a bright red heat steam is slowly decomposed by silicon: $\text{Si} + 2\text{H}_2\text{O} = \text{SiO}_2 + 2\text{H}_2$; at a higher temp., the decomposition is faster. The reaction is rapidly inhibited by the protective action of the crust of silica formed on the silicon.

H. Moissan found that fluorine attacks silicon at ordinary temp., *avec une vive incandescence*, and the heat of the reaction melts the silicon; but H. Moissan and J. Dewar observed that liquid fluorine is without action. J. J. Berzelius found that when ignited amorphous silicon is heated in chlorine it ignites and burns completely to form silicon chloride; W. Hempel and H. von Haasy said that silicon unites with chlorine at 340°-350°; L. Gattermann and K. Weinlig worked at 300°-310° in preparing silicon tetrachloride. F. Limmer said that commercial amorphous silicon is attacked by chlorine less readily than crystalline silicon, presumably because the former is contaminated with much more silica. E. Vigouroux said that combustion with incandescence occurs at 450° with chlorine; at 500° with bromine; and not at all with iodine; but at a red-heat iodine reacts *sans incandescence visible*. P. F. Spielmann found that boiling bromine has no action on graphitoid silicon; and A. Besson observed that iodine chloride and iodine bromide form the double halides (*q.v.*). In all cases where silicon reacts with the halogen, the corresponding halide is produced. The heats of reaction with crystalline silicon are:

	SiH_4gas	SiF_4gas	SiCl_4gas	$\text{SiBr}_4\text{liquid}$	SiI_4solid
Cals.	24.8	239.4	121.8	71.0	6.7

According to E. Vigouroux, G. S. Newth, and W. Hempel and H. von Haasy, gaseous hydrogen fluoride attacks silicon at ordinary temp., forming silicon tetrafluoride. H. Buff and F. Wöhler, and A. Besson obtained with dry hydrogen chloride at a red heat, a mixture of silico-chloroform, SiHCl_3 , and silicon tetrachloride, SiCl_4 ; L. Gattermann and K. Weinlig worked at 450°-500° for making silico-chloro-

form. E. Vigouroux found that analogous reactions obtain with **hydrogen bromide**, and **hydrogen iodide**. According to A. DuBoin and A. Gautier, when a mixture of silicon and alumina is heated with hydrogen chloride, a mixture of silica and aluminium chloride, but not silicon chloride, is formed; and generally, mixtures of alumina with boron, silicon, or carbon behave similarly towards hydrogen chloride. J. J. Berzelius' silicon- α was stated to dissolve in **hydrofluoric acid** with the evolution of hydrogen, while his silicon- β was not attacked by this acid. A form of silicon soluble in hydrofluoric acid was prepared by H. Moissan and F. Siemens, W. Manchot and co-workers, and by P. Lebeau—*vide supra*. V. Eggertz found that the silicon which crystallizes from many kinds of cast iron is soluble in hot hydrofluoric acid. H. St. C. Deville, F. Wöhler, and H. Moissan reported that ordinary crystalline silicon is not attacked by hydrofluoric acid. *Aucun acide dissout ou liquide, agissant isolément*, said E. Vigouroux, *n'attaque le silicium amorphe*. Dil. or conc., cold or boiling hydrofluoric acid or **hydrochloric acid** is without action; and under similar conditions neither **sulphuric acid** nor **nitric acid** has any action. J. L. Gay Lussac and L. J. Thénard, and J. J. Berzelius found that amorphous silicon is dissolved by a mixture of nitric and hydrofluoric acids; and H. St. C. Deville, F. Wöhler, and H. Moissan obtained similar results with crystalline silicon. P. F. Spielmann said that commercial graphitoidal silicon is not attacked by a mixture of sulphuric and hydrofluoric acids. E. Vigouroux found that hydrofluoric acid mixed with some oxidizing agents—*e.g.* nitric acid, **potassium chlorate**, **potassium nitrate**, etc.—or nitric acid mixed with some fluoride—*e.g.* potassium fluoride, etc.—attacks silicon at ordinary temp. A mixture of fuming nitric acid and potassium chlorate has no action on silicon. J. J. Berzelius said that the silicon is not changed by fused potassium chlorate. Probably the violent reaction occurs when the mixture is heated rapidly. Cold aqua regia is without action; at 100° hydrated silicon dioxide is formed. Many of the metal **fluorides**, **chlorides**, **bromides**, and **iodides** are decomposed when heated with silicon—*e.g.*, at a red heat, **silver fluoride** gives silver and silicon fluoride; $\text{Si} + 4\text{AgF} \rightarrow \text{SiF}_4 + 4\text{Ag}$, and similarly with lead and zinc fluorides; according to E. Vigouroux and F. Ducelliez, **potassium hydrofluoride** gives a mixture of potassium fluoride and fluosilicate: $\text{Si} + 4\text{KHF}_2 \rightarrow 2\text{KF} + 2\text{H}_2 + \text{K}_2\text{SiF}_6$. L. Lévy found that with **titanium chloride**, at a high temp., arborescent crystals of titanium silicide are formed. In other cases, with an excess of silicon, and at a high temp., a silicide may be formed. According to A. Besson, **sulphur chloride**, SCl_2 , at a red heat forms silicon thiochloride, SiSCl_2 ; and **sulphuryl chloride**, SO_2Cl_2 , at a red-heat, forms silicon tetrachloride and sulphur dioxide. H. Moissan and P. Lebeau found that **sulphuryl fluoride**, SO_2F_2 , acts in an analogous manner. A. Ditte found that amorphous silicon reacts with a conc. aq. soln. of **iodic acid** at 250° liberating iodine, and forming hydrated silicon dioxide; crystalline silicon reacts more slowly than amorphous.

J. J. Berzelius said that when silicon is heated in the vapour of **sulphur**, or when sulphur vapour is passed over silicon at a white heat, the combination is attended by incandescence and silicon sulphide is formed. E. Vigouroux said that the reaction begins at 600°; G. J. L. de Chalmot, at 300°. W. Hempel and H. von Haasy studied the reaction. According to E. Vigouroux, **hydrogen sulphide** at 400°–500°, or at the temp. of its dissociation, has no appreciable action on silicon, but at an elevated temp. silicon sulphide is formed. P. Sabatier found that at a dark red heat, **hydrogen selenide** forms silicon selenide. E. Vigouroux did not observe any appreciable reduction of **sulphur dioxide** by silicon at 1000°. For the action of **sulphuric acid**, *vide supra*. E. Wilke-Dörturt found that at an elevated temp., sulphuric acid is reduced by silicon to sulphur, and silicon dioxide is formed, but E. Vigouroux found that the boiling conc. acid has no action.

According to E. Vigouroux, H. Funk, and P. Schützenberger and A. Colson, **nitrogen** reacts with silicon at about 1000°, forming the nitride. The reaction was studied by L. Weiss and T. Engelhardt, H. Funk, and R. Formals; the former showed that the reaction begins at about 1300°, for the increase in weight, *w* grm. per

gram, which occurs when silicon is heated in nitrogen at θ° for 30 mins., is as follows:

θ	1240°	1295°	1300°	1310°	1320°	1400°	1480°
w	0.0001	0.0001	0.0001	0.0002	0.0014	0.0049	0.0061

At a bright red heat, E. Vigouroux found that **ammonia** reacts with silicon, forming the nitride, and liberating hydrogen. Aq. ammonia has no action on silicon. The **nitrogen oxides**— N_2O , and NO —are vigorously reduced above 800° . For the action of **nitric acid**, *vide supra*. P. Lebeau said that nitric acid (1:1) at 100° does not attack very finely divided silicon; nor did E. Vigouroux observe any reaction with the boiling fuming acid. W. Manchot found nitric acid attacks silicon in a soln. of silicon in silver. The slowly-cooled, insoluble silicon inflames in contact with cold nitric acid. No chemical action occurs when silicon is heated in contact with **phosphorus**, **arsenic**, or **antimony** at the temp. at which these elements are distilled; and at a red heat, **phosphorus pentoxide**, **arsenic trioxide**, and **antimony trioxide** are reduced by silicon. L. Kahlenberg and W. J. Trautman observed no reduction with arsenious or phosphoric oxides, but they found antimony trioxide and **bismuth trioxide** were reduced by silicon. M. Wunder and B. Jeanneret found that after 3 hrs. treatment with **phosphoric acid** of sp. gr. 1.75, at 230° , silicon dissolves, forming a colourless liquid with a gelatinous substance in suspension. Any carbon present remains undissolved.

H. Moissan and A. Stock, E. Vigouroux, and O. P. Watts found that **boron** unites with silicon at a very high temp., forming silicon boride (*q.v.*). J. J. Berzelius said that molten **boric oxide**, or **borax**, has little or no action on silicon. For the action of **carbon** on silicon, *vide* the carbides. H. Moissan found that molten silicon at 1200° – 1400° dissolves carbon. K. Nischk studied the affinity of carbon for silicon; and G. Tammann and K. Schönert, the diffusion of carbon in silicon. P. Schützenberger and co-workers found that carbon monoxide is slowly absorbed by silicon at a white heat, forming a silicon carboxide, and if oxidizing gases are excluded silicon carbide is formed. E. Vigouroux found carbon monoxide not attacked by silicon at 1200° ; but **carbon dioxide** is reduced to carbon monoxide at 800° – 1000° . P. Schützenberger and A. Colson found that at a white heat carbon dioxide is absorbed by silicon, forming silicon carboxide; they also found that silicon, in an atm. of **cyanogen**, forms silicon carbonitride. A. C. Vournasos found that at a white heat a mixture of carbon and silicon, in an atm. of nitrogen, formed **sodium formate**, which gives nascent hydrogen when heated, does not react with silicon.

Silicon dissolves in many molten **metals**, forming silicides—*vide infra*. In general, the affinity of silicon for oxygen exceeds that of the other metals excepting those of the alkalis and alkaline earths, boron, and aluminium. Accordingly, a great many **metal oxides** are reduced by silicon at a high temp. Some **metal sulphides** behave similarly. E. Vigouroux reduced the oxides of copper, mercury, tin, lead, bismuth, manganese, and iron by heating them with silicon; the reaction is sometimes attended with incandescence. C. Winkler obtained lead silicate by heating lead oxide with crystalline silicon. H. N. Warren also reduced the oxides of lead, chromium, molybdenum, and tungsten by heated silicon. C. Tammann reduced **metatitanic acid** to a lower oxide by means of silicon at an elevated temp.: $2TiO(OH)_2 + Si = SiO_2 + H_2 + H_2O + Ti_2O_3$. Anhydrous **titanic oxide**, TiO_2 , and the hydrated **oxides of silicon, zirconium, and thorium**, are not affected. H. Moissan found that molten **calcium oxide** reacts with silicon, forming a basic calcium silicate. L. Kahlenberg and W. J. Trautmann, and H. Goldschmidt reduced **barium oxide** by heating it with silicon; but not so with **calcium, strontium, beryllium, magnesium, or aluminium oxides**. **Lithium carbonate** is slightly reduced. J. J. Berzelius found that a vigorous reaction occurs when amorphous silicon is mixed with **potassium or sodium hydroxide** and heated to

the m.p., hydrogen being evolved; the reaction is feebler with barium hydroxide, and feebler still with calcium hydroxide. H. St. C. Deville said that crystalline silicon is slowly attacked by fused potassium hydroxide; C. Winkler said that the attack is rapid. F. Wöhler, and H. Moissan and F. Siemens, and H. Moissan and A. Stock found that a soln. of potassium or sodium hydroxide attacks crystalline silicon in the cold, and when warmed silicon is slowly dissolved with the evolution of hydrogen—*vide* 1, 7, 2.

According to J. J. Berzelius, when a mixture of amorphous silicon and an alkali carbonate is heated, a vigorous reaction attended by incandescence occurs, carbon separates and carbon monoxide is evolved, and the smaller the proportion of alkali carbonate, the lower the temp. of the reaction; with a large proportion of alkali carbonate, the reaction occurs without incandescence and without the separation of carbon, but with the evolution of carbon monoxide. H. St. C. Deville, and F. Wöhler also found crystalline silicon reacts with incandescence with alkali carbonates when heated, forming carbon, carbon monoxide, and alkali silicate. E. Vigouroux said that amorphous silicon reacts with the alkali carbonates, in aq. soln. or in a molten state, forming silicon dioxide, or silicate. J. J. Berzelius said that amorphous silicon is slowly attacked by fused potassium nitrate and gases are evolved; E. Vigouroux also said that potassium nitrate at its temp. of decomposition reacts with amorphous silicon. P. F. Spielmann said that fused potassium nitrate does not attack commercial graphitoidal silicon. As a rule, mixtures of silicon with oxidizing agents—lead chromate, potassium dichromate, etc.—react vigorously when heated to redness. L. Kahlenberg and W. J. Trautmann found that various chromates are reduced by silicon; the molybdates and tungstates are only partially reduced; silver, mercury, chromic, copper, lead, and stannous oxides are readily reduced; not so with stannic oxide. Tungstic and molybdic oxides are reduced to the lower oxides, but not to the metal; lead sulphate and lead chloride are reduced to the metal, lead borate reacts with silicon, but no metal globules were formed; boric oxide is not reduced by silicon. E. Vigouroux found lead sulphate, and calcium phosphate are reduced by silicon when heated. According to P. Lebeau, a 10 per cent. soln. of cupric chloride, ammonium or potassium cupric chloride, cupric sulphate, chromic acid, or ferric or ferrous chloride does not attack amorphous silicon. L. Kahlenberg and W. J. Trautmann also examined the reactions of silicon with many inorganic salts.

§ 6. The Atomic Weight and Valency of Silicon

According to D. I. Mendeléeff,¹ "the composition of silica has been the subject of the most contradictory statements in the history of science," and J. C. G. de Marignac could say that *il n'y aucun corps simple dont le poids atomique offre plus d'incertitude que le silicium*. Near the beginning of the nineteenth century, the composition of silica was variously represented:

	SiO or Si ₂ O ₂	SiO ₂	SiO ₃
At. wt. (O = 16) .	14	28	42
Eq. wt. (O = 8) .	7	14	21

Differences of opinion grouped mainly about SiO₂ and SiO₃ as the best representative formulae for silica. J. J. Berzelius' analyses showed that eight parts of oxygen by weight were united with seven parts of silicon, and at first the formula was written SiO. The formula SiO was proposed by T. Thomson, and was supported by J. B. A. Dumas, and J. J. Ebelmen from arguments suggested by the constitution of the silicic esters. No satisfactory guide to the selection of the at. wt. was available before Avogadro's hypothesis had been recognized as a criterion. The significance of J. B. A. Dumas' determination of the vap. density of silicon tetrachloride, made in 1826, was not recognized by J. B. A. Dumas himself even in 1857, for he then gave the formula SiO₃, whereas the vap. density of the tetrachloride, 5.94 (air unity), corresponds with 29.7 as the smallest unit of silicon present in this compound. J. J. Ebelmen's work on the ethyl silicates could not be satisfactorily interpreted when the formula of silica was assumed to be SiO₃, for the ratio of the oxygen in ethyl oxide to the oxygen in the silica in these compounds is as 1:1, 1:2, and 1:4. J. J. Berzelius' analyses of various silicates showed that the ratio of oxygen in the base to the oxygen in the acid commonly varied from 2:1 to 1:3, and he accordingly argued that in the trisilicates, where the ratio is 1:3, the potassium oxide and alumina are united with silica in the same way that the potassium oxide and alumina are united with sulphur trioxide in the alums. By analogy, therefore, the formulae for felspar and alum were considered to be similar:

The argument is not valid since the trisilicates are not normal salts of silicic acid, but rather acid salts, because they contain the largest proportion of acid to base, and are usually found in nature side by side with free silica. H. Kopp based an argument for the formula SiO₃ on the volatile chlorides and bromides. The differences between the b.p. of chloroform, CHCl₃, and bromoform, CHBr₃, is about 96°; there is a similar difference between the b.p. of phosphorus trichloride, PCl₃, and tribromide, PBr₃; and between silicon chloride and bromide, hence the formulae of the latter should be SiCl₃ and SiBr₃ respectively, corresponding with the system of chemical equivalents then in use, and with Si₂O₃ for silica. H. Kopp, however, later showed that evidence of this kind is quite unreliable because the difference of 32° per atom of chlorine displaced by bromine is not general. J. I. Pierre prepared what were regarded as a number of chlorosulphides

by the action of hydrogen sulphide on silicon chloride, and he considered that the results were best interpreted on the assumption that the formula of silica is SiO_3 , but he mistook silicon trichloro-hydrosulphide, $\text{SiCl}_3\cdot\text{SH}$, for SiSiCl_2 .

H. Rose studied the action of silica on fused sodium carbonate, and he showed that an eq. of silica displaced an eq. of carbon dioxide if the formula of silica be SiO_3 , while if the formula be SiO_2 , 1.5 eq. of carbon dioxide are displaced. The erroneous assumption was made that the eq. of carbon dioxide evolved is equal to the eq. of the silica added. He found the assumption that the formula of silica is SiO_2 to give the simpler results. If the same argument were applied to niobic and tantalic acids an erroneous conclusion might be obtained because the amount of carbon dioxide expelled really depends on the temp.; indeed, as showing the unreliability of the argument, T. Scheerer concluded that the formula is SiO_3 from his observations on the behaviour of silica towards the alkali carbonates; he considered that the silicates could be better represented by regarding silica as SiO_3 than as SiO_2 . F. von Kobell, in 1871, and F. A. Quenstedt, as late as 1877, supported T. Scheerer in this respect. P. Yorke's experiments led him to conclude that there are at least two silicic acids with different eq. M. A. Gaudin arguing from (i), the vapour densities of silicon chloride and fluoride; and (ii) the analogies which silica bears to stannic and stannous oxides, advocated the formula SiO_2 . O. B. Kühn, A. Würtz, C. Weltzien, and L. Gmelin favoured the formula SiO_2 ; and P. Einbrodt compared the results obtained by representing the composition of the minerals by silica considered as SiO_2 and as SiO_3 , and claimed that the former gave the more advantageous results. He also emphasized the evidence in favour of this formula derived from the vapour densities of the silicon halides, and from the displacement of carbon dioxide in the carbonates by silica. J. C. G. de Marignac, in his memoir: *Sur l'isomorphisme des fluosilicates et des fluostannates et sur le poids atomique du silicium*, showed that the sp. ht. rule could not be used to estimate the at. wt. of silicon because of the variability of the sp. ht. with temp. and allotropic state. He explained the isomorphism of the fluostannates and fluosilicates, by assuming that the formula for silicon fluoride is SiF_4 analogous with SnF_4 for stannic fluoride. He later showed that the fluotitanates and fluozirconates should be included in the same isomorphous series. These conclusions were confirmed by the work of C. Friedel and co-workers on the volatile compounds of silicon and carbon—*vide infra* in connection with the silicon hydrides. F. S. Kipping obtained evidence of the formation of a silicon hydrocarbon, $\text{Si}(\text{C}_6\text{H}_5)_2\cdot\text{Si}(\text{C}_6\text{H}_5)_2\cdot\text{Si}(\text{C}_6\text{H}_5)_2\cdot\text{Si}(\text{C}_6\text{H}_5)_2$, in which two of the four silicon atoms may be tervalent.

Silicon is now regarded as a quadrivalent element, and the formula of silica is accordingly represented by SiO_2 , because of (i) the vapour density of the volatile silicon compounds—Avogadro's law; (ii) the at. ht. determined by H. F. Weber at 232° , approximates to Dulong and Petit's rule; (iii) the isomorphism of the complex fluorides of silicon, titanium, zirconium, and tin—Mitscherlich's rule; and (iv) the position of silicon in the periodic table in the fourth group between carbon and titanium, and in the second horizontal series between aluminium and phosphorus, is particularly suited for an element with the properties possessed by silicon. There are very few compounds in which silicon is said to exhibit a valency lower than that of a tetrad. W. Barlow and W. J. Pope inferred from the absence of isomorphism between silicon and carbon compounds, and the similarity on the morphotropic behaviour of silicon with the bivalent elements, that carbon is unique in possessing a fundamental valency as large as 4, and that silicon is essentially bivalent. G. Jerusalem supports this hypothesis—*vide* 1. 5, 18.

J. J. Berzelius determined the amount of oxygen required to oxidize the impure amorphous silicon which he had prepared, and from this he calculated that the at. wt. of silicon—translated into modern units—is 19.6; and he later obtained the values 26.3, and 29.0. In a table published in 1814, he gave the at. wt. 32.46; and 1815, 23.11. In 1811, F. Stromeyer, also working with an impure sample of silicon, obtained 27.25 . Between 1815 and 1826, J. J. Berzelius analyzed hydro-

fluosilicic acid, by converting it into the barium salt, and obtained 29.6. He obtained 31.3 to 31.6 as a result of the analysis of aluminium silicate; and 29.63 by the oxidation of a sample of silicon purified by washing with hydrofluoric acid. T. J. Pelouse, J. B. A. Dumas, and J. Schiel decomposed silicon tetrachloride by water; the first two determined the liberated hydrochloric acid by titration with standard silver nitrate, and the last, by precipitation as silver chloride. From the ratio $\text{SiCl}_4 : 4\text{Ag}$, T. J. Pelouse obtained 28.39, J. B. A. Dumas 28.09, and O. Höning-schmid and M. Steinheil 28.105; while from the ratio $\text{SiCl}_4 : 4\text{AgCl}$, J. Schiel obtained 27.96. H. St. C. Deville transformed silicon into alkali silicate, and from the ratio $\text{K}_2\text{O} : \text{SiO}_2$, obtained 30.4 for the at. wt. C. Winkler likewise heated silicon with (i) potassium hydroxide, (ii) sodium carbonate, and (iii) an aq. soln. of potassium hydroxide, and obtained values varying from 28.9 to 29.4 for this constant. The above determinations may be considered to conclude the older and less reliable determinations of the at. wt. of silicon. According to T. E. Thorpe and J. W. Young, the only reliable values for the at. wt. of silicon are based upon the analysis of the silicon halides which appear to be the most suitable of all compounds of silicon for at. wt. determinations when suitable precautions are taken; they showed that colloidal silica interferes with the titration of hydrobromic acid in the liquid obtained by the decomposition of silicon tetrabromide in water; and they determined the weight of the silica produced in the reaction, and calculated the at. wt. 28.385 from the ratio $\text{SiBr}_4 : \text{SiO}_2$. Similarly, W. Becker and J. Meyer obtained 28.225 for the ratio $\text{SiCl}_4 : \text{SiO}_2$. G. P. Baxter and co-workers analyzed silicon tetrachloride and silicon tetrabromide and obtained consistent values agreeing with 28.063 to about one part in two thousand. In another set based on the analysis of the tetrachloride, 28.111 was obtained. A. Stock and E. Kuss obtained 28.15 by using the reaction $\text{SiH}_4 + 2\text{NaOH} = \text{Na}_2\text{SiO}_3 + 2\text{H}_2$. The International Atomic Weights Committee use 28.3 as the best representative value for the at. wt. of silicon. B. Brauner calculated 28.3 for the best representative value, and F. W. Clarke, 28.25. F. M. Jüger and D. W. Dijkstra found no difference in the general properties of terrestrial and extraterrestrial silicon from meteorites, and hence inferred that the ratio of the isotopes must be the same whatever be the origin of the silicon.

H. von Jüptner found the mol. wt. of silicon dissolved in iron corresponds with a seven-atom mol. The effect of silicon on the f.p. of copper shows that in molten copper the mol. of silicon is possibly monatomic. The formation of silicide may spoil the inferences. E. Rutherford and J. Chadwick² obtained evidence of the emission of long-range particles when α -particles act on silicon; but G. Kirsch and H. Pettersson obtained evidence of the emission of hydrogen nuclei by bombarding silicon with α -rays; L. F. Bates and J. S. Rogers made observations on this subject. According to F. W. Aston, silicon furnishes three isotopes, one of at. wt. 28, and the others of at. wt. 29, and 30. R. S. Mulliken obtained evidence of the two isotopes in the band spectrum of silicon nitride.

S. Brown³ assumed that the silica in plants is derived from the transmutation of carbon into silicon by the plant; J. J. Berzelius, however, attributed the appearance of this element to the slight solubility of silicic acid in the water taken in by the roots of the growing plants. S. Brown believed that when paracyanogen is heated out of contact with air, alone or in contact with potassium carbonate, platinum, or other substances having a strong attraction for silicon, its nitrogen atoms pass away unchanged, while its carbon atoms unite together and form silicon. G. J. Knox argued that the nitrogen is the source of the silicon in S. Brown's experiment; he regarded nitrogen as a compound of silicon and hydrogen, because he obtained silicon under similar conditions to those described by S. Brown, but with substances containing no carbon—*e.g.* potassium amide, KNH_2 , which he called "ammonia-nitruet of potassium." G. Wilson and J. C. Brown obtained silicon in a number of cases under conditions which they said "preclude the possibility of its being derived as an impurity or accidental ingredient from the vessels or materials or reagents made use of." T. Gross thought that he had transformed silicon into carbon by the electrolysis of an aq. soln. of an alkali silicate between silver electrodes. Subsequent observations by J. D. Smith and R. H. Brett, etc., have failed to establish these results; if no silicon be present in the system, none is formed.

§ 7. The Silicides of the Alkali and Copper Families of Elements

The binary compounds of silicon with the electropositive elements, more particularly the metals, are called **silicides**. Their chemistry attracted but little attention until H. Moissan investigated their formation in the electric furnace. A few can be prepared at low temp., and many are found as metallurgical by-products. There appears to be a somewhat similar relation between the carbides and silicides to that which subsists between carbon and silicon. Many of the methods of preparation of the carbides can be employed for the silicides; the most important methods depend on (i) the direct union of the elements at a high temp. E. Vigouroux said that the alkali metals, zinc, aluminium, lead, tin, antimony, bismuth, gold, and silver do not combine directly with silicon even in the electric furnace; while iron, chromium, nickel, cobalt, manganese, copper, and platinum combine directly with silicon to form crystalline silicides. (ii) The reduction of the metal oxide by silicon; (iii) the reduction of the metal silicate or a mixture of the metal oxide and

by carbon; (iv) the reduction by a metal like sodium, magnesium, or aluminium; (v) the action of a siliceous compound in presence of the free metal or metal oxide; (v) the action of a silicon halide on a metal; or (vi) the dissolution of a metal in copper silicide. Most of the metal silicides readily crystallize; and they are not so active chemically as the carbides. Most of them are fairly stable in contact with water—the silicides of lithium and of the alkaline earths are alone decomposed by water. The metal silicides usually form well-defined crystals with a brilliant metallic lustre; they are usually hard, and possess a high m.p. The silicides are not generally so chemically active as the carbides. At a dull red heat, when heated in oxygen, the silicides may be attacked superficially, or they may resist attack altogether. The chemical properties are of course dependent upon the contained metal; lithium silicide, for instance, is easily oxidized. The aluminium, magnesium, alkaline earth, and the alkali silicides are attacked by dil. acids.

The following monographs deal with the silicides: O. Hönigschmid, *Karbid und Silicide*, Halle a. S., 1914; P. Lebeau, *Le Silicium et ses combinaisons artificielles*, Paris, 1899; E. Vigouroux, *Le silicium et les silicides métalliques*, Paris, 1896; H. Moissan, *Le four électrique*, Paris, 1897; London, 1904.

According to J. J. Berzelius,¹ potassium unites with silicon without perceptible incandescence. The compound containing a larger proportion of potassium than silicon is dark greyish-brown, and dissolves entirely in water evolving hydrogen, and yielding potassium silicate. The compound containing more silicon than potassium is obtained by decomposing silicon fluoride by potassium, and it leaves a residue of silicon when digested in water. If potassium vapour be passed over heated silica, potassium silicide and silicate are formed, and dissolve in water without leaving any residue; but if the greater part of potassium be previously expelled by heat, the remaining vitreous mass when digested first in water and then in hydrofluoric acid, leaves a little silicon behind. H. St. C. Deville doubted J. J. Berzelius' inference that he had prepared potassium silicide in these experiments. He also said:

The many experiments which I have made with sodium have convinced me that any combination of this kind does not exist; at any rate, the silicon can retain only a minute quantity of sodium.

C. Winkler also stated that crystalline silicon does not absorb the vapour of potassium or sodium either when feebly or strongly heated. H. Moissan, however, said that silicon is attacked superficially by the vapour of the alkali metal, forming a little potassium or sodium silicide as the case may be; but E. Vigouroux found that when silicon and sodium or potassium are heated together in sealed tubes, no combination occurs at temp. up to that at which the alkali metal volatilizes. No silicide of sodium, potassium, rubidium, or caesium has yet been prepared. H. Moissan found lithium silicide, Li_2Si_2 , to be formed when silicon and lithium are heated in vacuo for 2 or 3 hrs., and finally at dull redness. The excess of lithium is removed either by treating the product with liquid ammonia which dissolves free lithium as the so-called lithium ammonium, or by distilling off the free lithium at $400^\circ\text{--}500^\circ$ under reduced press. Lithium silicide forms small, lustrous crystals of a deep indigo-blue, has a sp. gr. 1.12, and is decomposed in a vacuum above 600° into lithium and amorphous silicon. Hydrogen, above 600° , yields, with the silicide, lithium hydride and silicon. When warmed in gaseous fluorine, a reaction takes place with incandescence, producing lithium and silicon fluorides; with chlorine, bromine, and iodine, the reaction is similar, but a higher temp. is required before it begins. Heated in air, it burns and melts; in oxygen, much light and heat are developed. It reacts with molten sulphur with great vigour, a lithium polysulphide and a sulphide of silicon being formed; the last-mentioned substance is decomposed by cold water with evolution of hydrogen sulphide. Selenium, tellurium, and phosphorus all attack the silicide with production of incandescence. Arsenic and antimony form crystalline alloys only

slowly attacked by cold water. Lithium silicide reduces the oxides of iron, chromium, and manganese, alloys being produced. When the silicide is placed on sulphuric acid, it becomes incandescent, hydrogen sulphide is evolved, and sulphur formed. With nitric acid, it reacts explosively, producing nitrogen peroxide and silica. With hydrochloric acid, the silicide becomes incandescent and ~~there~~ is coated with hydrated silica; at low temp. or when dil. acid is used, a gas spontaneously inflammable in air is evolved; it burns with a very white flame and deposits amorphous silica; an ethereal soln. of hydrogen chloride has no action on the silicide. The reaction with water is very violent; a spontaneously inflammable gas is evolved, and a soln. of lithium hydroxide containing silica in suspension is obtained. If the reaction is moderated by covering the silicide with glycerol, pure hydrogen is evolved. With aq. soln. of alkali hydroxides, only hydrogen is evolved. It appears that water always decomposes the silicide with formation of hydrogen and a hydrogen silicide, Si_2H_6 ; the latter is decomposed by the alkali hydroxides.

The affinity of silicon for copper, said G. J. L. de Chalmot,² is small, and is less than it is for iron, manganese, and chromium, nearly the same as it is for silver, and perhaps a little less than it is for zinc; M. Philips also said the affinity of silicon for copper is smaller than it is for hydrogen and carbon, and, added W. Hampe, smaller than it is for fluorine. M. Philips said that the two elements begin to react at about 775°. In 1810, J. J. Berzelius obtained an alloy of copper with 2.3 per cent. silicon, by heating a mixture of silica, carbon, and copper turnings in a closed crucible at a white heat; and in 1823, he made alloys richer in silicon by dissolving silicon in molten copper. According to M. Philips, the production of *cuprosilicon*, as alloys of copper and silicon are called in commerce, from the constituent elements, using an excess of silicon, does not give a homogeneous product, but if an excess of copper is used, homogeneous alloys can be readily obtained. The ready oxidizability of amorphous silicon makes it unsuited for the work. A mixture of 100 grms. of copper and 20 grms. of silicon gave an alloy with 13.28 per cent. of silicon and 85.8 per cent. of copper; and a mixture of 150 grms. of copper and 22.5 grms. of silicon gave an alloy with 87.17 per cent. of copper and 11.96 per cent. of silicon; while a mixture of 100 grms. of copper and 10 grms. of silicon gave an alloy with 90.69 per cent. of copper and 9.02 per cent. of silicon. The copper turnings and powdered silicon were placed with silicon below the copper in a graphite crucible and heated to about 1150°–1250° for about 2 hrs. The mixture was frequently stirred. The mixture during fusion was covered with a layer of equimolar parts of potassium and sodium chlorides; borax was found not to be so good. Alloys were also made from the constituent elements by H. N. Warren, W. Hampe, E. Vigouroux, W. Manchot and H. Funk, H. Behrens, K. Nischk, and E. Rudolf. H. Goldschmidt obtained cuprosilicon in a thermite reaction between cupric oxide and silicon. C. Heusler fused copper with siliceous pig-iron—ferrosilicon—removed the two upper layers which formed when the molten mass was allowed to stand, and found that cuprosilicon remained at the bottom. A. Sanfourche said that it is impossible to prepare alloys with over 12.10 per cent. of silicon, and that in consequence all formulæ professing a higher proportion of silicon should be deleted from literature.

As indicated above, J. J. Berzelius obtained cuprosilicon by heating a mixture of copper, carbon, and silica; A. Dick used a similar process. W. Feld and G. von Knorre made a mixture of copper—the eq. amount of cupric oxide—kieselguhr, and sodium chloride into briquettes, with tar as a bond; the briquettes were carbonized at a dull red heat, and smelted with a flux of quartz and lime; the resulting alloy contained 8 per cent. silicon; if fluorspar be used in place of sodium chloride, the product has 7 per cent. silicon. E. H. and A. H. Cowles and C. F. Mabery heated copper with an excess of sand and wood charcoal in an electric furnace; and G. J. L. de Chalmot, and G. Kroup, recommended a similar process. W. Rathenau heated in an electric furnace a mixture of copper or copper oxide, lime, carbon, and sand. The products were calcium carbide and cuprosilicon. C. Matignon and R. Trannoy heated a mixture of copper silicate and aluminium;

O. P. Watts reduced copper ore in presence of a silicate by means of calcium carbide or aluminium in an electric furnace; and M. Phillips heated an intimate mixture of cupric oxide and silicon carbide for 5 hrs. in a coke furnace; H. St. C. Deville and H. Caron heated together potassium fluosilicate, sodium, and copper turnings and obtained an alloy with 12 per cent. of silicon; and L. Weiller used a mixture—potassium fluosilicate (450), glass (600), sodium chloride (250), sodium carbonate (75), calcium chloride (500), and calcium carbonate (60)—intended to produce its own sodium. E. Vigouroux obtained cuprosilicon by the action of silicon tetrachloride on copper at 1200°; and A. Dufour obtained a red precipitate containing copper and silicon by passing silicon tetrahydride into a soln. of cupric sulphate.

H. N. Warren prepared a cuprosilicon by the electrolysis of molten potassium fluosilicate with molten copper as cathode. He thus obtained a brittle alloy of the two elements. J. Walter electrolyzed molten potassium silicate, at a temp. above the m.p. of cuprosilicon, by using a molten copper cathode, and a carbon anode. The potassium silicate can be fluxed by the addition of potassium carbonate or chloride, sodium silicate, etc. A. G. Betts obtained cuprosilicon as a by-product by electrolyzing a molten mixture of clay, copper, and alumina sat. with cryolite—aluminium formed at the cathode accumulated on the surface of the bath, and cuprosilicon formed at the anode collected at the bottom of the bath.

Partial observations on the constitution of the copper-silicon alloys have been made by E. Vigouroux, P. Lebeau, G. J. L. de Chalmot, W. Hampe, and M. Phillips.

The equilibrium diagram, Fig. 7, was obtained by M. Rudolphi. He believes that only two compounds are formed, Cu_3Si , and $\text{Cu}_{13}\text{Si}_4$; and that the latter is produced by secondary changes in the solidified alloy. The compounds reported by E. Vigouroux, and P. Lebeau are considered to be eutectic mixtures. The f.p. curve shows a maximum about 855° and 13 per cent. by weight of silicon, corresponding with the compound Cu_3Si , two eutectic points at 825° and 9.8 per cent. and 800° and 18.3 per cent. by weight of silicon, and a break at 849° and 7.8 per cent. of the same element. A. Sanfourche believes that $\text{Cu}_{13}\text{Si}_4$ better represents the formula of E. Rudolphi's tritasilicide.

Returning to Fig. 7, from 0-4.5 per cent. of silicon, mixed crystals separate; a second series of solid soln. from 7.34-8.3 per cent. of silicon are only stable within narrow limits of temp. Two reactions take place during the cooling of the crystallized alloy: the solid soln. sat. at 7.34 per cent. of silicon decompose at 815°-780° into two other series of solid soln., one of which splits up at 710° into the compound $\text{Cu}_{13}\text{Si}_4$ and the solid soln. first mentioned. It looks as if there is a misinterpretation of the results in E. Rudolphi's experiments. The results have been criticized by W. Guertler, and A. M. Portevin. K. Bornemann considers the individuality of E. Rudolphi's copper tetrasilicide, $\text{Cu}_{13}\text{Si}_4$, is very doubtful. R. Frilley found no signs of it on the sp. gr. curve of the alloys.

According to P. Lebeau, commercial cuprosilicon contains large and small crystals of silicon, some steel-grey crystals of ferrosilicon and a matrix of copper tetrasilicide, Cu_4Si_7 , not the hemisilicide, as stated by G. J. L. de Chalmot, and E. Vigouroux in 1896. The latter prepared the tetrasilicide by fusing 17 parts of silicon and 90 parts of copper in a current of hydrogen, and removing any silica from the product by treatment with a 5 per cent. soln. of sodium carbonate. He heated to 1200° in a stream of hydrogen, 81.74 grms. of copper, 28.26 grms. of crystalline silicon, and 200 grms. of lead, bismuth, or antimony. He found that the maximum amount of silicon retained by the copper is about

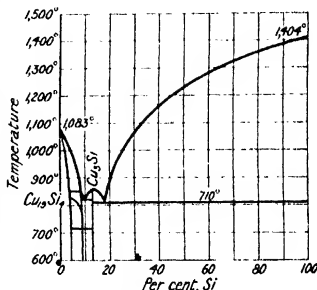

Fig. 7.—Equilibrium Diagram of Silicon and Copper.

10 per cent., any in excess is present as free silicon; this amount of silicon corresponds with the formation of the tetrakisilicide; and in the presence of lead and bismuth, the tetrakisilicide rises to the surface, but in the case of antimony it remains disseminated throughout the mass. E. Vigouroux passed silicon tetrachloride over copper at 1200° and obtained cuprosilicon with less than 5 per cent. of combined silicon; by repeating the treatment, the combined silicon was carried up to about 10 per cent. R. Frilley found no sign of this compound on the sp. gr. curve. Copper tetrakisilicide has a metallic silver-white appearance which rapidly darkens, becoming first yellow and then brick-red. It is hard, brittle, and easily powdered; the fracture is tin-white and fine-grained; the sp. gr. is 7.48 at 0° ; and that of the fused silicide is 7.58 . P. Lebeau gave 850° for the m.p. With water, this silicide develops hydrogen; chlorine attacks it below a red heat; it is readily attacked by warm dil. or conc. nitric acid or by a mixture of nitric and hydrofluoric acids; but hydrochloric, sulphuric, or hydrofluoric acid has scarcely any action on the compound. Hot conc. sulphuric acid is coloured blue and silica separates; aqua regia attacks the alloy in the cold, and more rapidly when heated. Hot alkali-lye has very little action, and when boiled with a 5 per cent. soln. of sodium hydroxide, the grains of the tetrakisilicide are covered with a dirty grey film. H. Behrens said that the silicide is attacked by a mixture of hydrochloric acid and potassium chlorate, and that aq. ammonia preferentially attacks the copper, and a hot soln. of potassium hydroxide preferentially attacks the constituents rich in silicon. According to P. Lebeau, this is the only definite compound of copper and silicon which can be detected by the cooling curves of the alloys; E. Rudolf said that, excepting the less definite $\text{Cu}_{10}\text{Si}_4$, copper trisilicide, Cu_3Si , is the only compound shown on the cooling curves. R. Frilley found evidence of it on the mol. vol. curve of the alloys. H. St. C. Deville and H. Caron prepared this compound accidentally in their study of the action of silicon tetrachloride vap. on sodium placed in a copper boat.

M. Philips reported the formation of copper diheptasilicide, Cu_7Si_2 , to be formed as a residue after treating the trisilicide with 20 per cent. potash-lye for 5 hrs. on a water-bath. W. Guertler believes this product to be a mixture. M. Philips also reported copper dipentasilicide, Cu_5Si_2 , to be formed, but this was not isolated. R. Frilley obtained evidence of the existence of this compound on the mol. vol. curve; and of copper ditritasilicide, Cu_3Si_2 , a point of inflexion on the sp. gr. curve of the alloys. E. Vigouroux, C. Matignon, and G. J. L. de Chalmot prepared what was regarded as copper hemisilicide, Cu_2Si , by heating copper with an excess of sand and wood-charcoal in an electric furnace, the crystalline mass approximated Cu_2Si_2 , and when treated with aqua regia gave a residue with a composition Cu_2Si . L. Kahlenberg and W. J. Trautmann reported this compound. E. Vigouroux heated a mixture of copper with 10 per cent. silicon in an electric furnace until the excess of copper had volatilized. The steel-grey crystals had a sp. gr. of 6.9 at 18° . R. Frilley found evidence of this compound as a point of inflexion on the sp. gr. curve; and of copper silicide, CuSi , on the mol. vol. curve. E. Rudolf considers that the alleged compound is really a eutectic. G. J. L. de Chalmot reported the occurrence of copper trihemisilicide, Cu_3Si_3 , in a commercial sample of cuprosilicon. R. Frilley regarded a point of inflexion on the sp. gr. curve as evidence of the existence of this compound; and on the mol. vol. curve, he found evidence of copper tetrasilicide, CuSi_4 . The chemical individuality of none of these products has been established.

*According to W. Hampe, copper with 0.526 per cent. of silicon preserves its colour; F. Rudolf said the colour with one per cent. of silicon is like that of brass; those with 1.5 to 2 per cent. of silicon are yellowish-red, those with 3.5-4.8 per cent. have a pale bronze colour; and those with about 5 per cent. are pale brass-yellow, or, according to E. H. and A. H. Cowles and C. F. Mabery, greyish-black; those with 8 per cent. silicon are silver-white; and those with up to 10 per cent. are silver-white with a bluish tinge. H. St. C. Deville and H. Caron say that those with 12 per cent. silicon have a reddish tinge like bismuth; and C. Winkler said those with 20-30 per cent. silicon are grey. H. Behrens said that the microstructure of alloys with 0.5 per cent. silicon shows a grey network. W. Hampe said the fracture of an alloy with 3.66 per cent. silicon is compact and lustrous; with 6 per cent.,

crystalline and pale grey; with 8 per cent., conchoidal; and with 11·7 per cent., glassy. Observations have also been made by E. Vigouroux, A. Dick, S. Bogdan, and M. Philips. A. L. Norbury measured the vol. of the solute atoms in solid soln. of cuprosilicon. The sp. gr. of cuprosilicon alloys have been measured by A. Dick, W. Hampe, G. J. L. de Chalmot, etc.

Per cent. silicon	9·10	12·07	13·24	20·52	40·48
Sp. gr.	7·810	7·034	6·764	5·966	4·998

According to R. Frilley:

Per cent. Si	0	13·50	17·98	27·92	34·88	48·80	68·00	90·50	100·00
Sp. gr.	8·80	7·78	6·90	6·33	5·61	4·02	3·15	2·54	2·40
Mol. vol.	7·21	6·97	7·35	7·35	7·85	9·75	10·27	11·77	11·66

The decrease in sp. gr. is fairly regular with increasing proportions of silicon. The hardness of cuprosilicon at first increases rapidly with increasing proportions of silicon; and afterwards the increase is slower; observations were made by H. St. C. Deville and H. Caron, C. Winkler, G. J. L. de Chalmot, M. Philips, etc. H. Behrens said that the hardness of a 2·1 per cent. alloy is 3·1; of a 3 per cent. alloy, 3·0 for the crystals and 3·3 for the matrix; the numbers are respectively 3·2 and 3·4 for a 5 per cent. alloy; and for a 10 per cent. alloy, over 6 for the graphite-like crystals, 4 for the yellow prisms, and 4·2 for the matrix. E. Rudolphi said that quenching and slow cooling have little influence on the hardness. W. Hampe found the tensile strength of 0·53 and 3·47 per cent. silicon alloys to be respectively 50 and 95·3 kgms. per sq. mm.; he also found the malleability decreases with increasing content of silicon; the ductility of an alloy with 0·53 per cent. of silicon was like copper, a 2 per cent. alloy could still be drawn readily, but a 3·66 per cent. alloy was difficult, an alloy with 6 per cent. of silicon is brittle, and one with 11·7 per cent. of silicon behaved like glass. E. Wilson found the linear coeff. of thermal expansion to be 0·0000234–0·0000240 for alloys with 1·5–2·0 per cent. of silicon. H. St. C. Deville and H. Caron found alloys with 4·8 per cent. of silicon melted like bronze, and those with 12 per cent. of silicon melted more easily than silver. For E. Rudolphi's observations, *vide* Fig. 7. C. Heusler, and E. H. and A. H. Cowles and C. F. Mabery found that cuprosilicon is a good electrical conductor; W. Hampe said that alloys with 0·53 and 3·47 per cent. of silicon have respectively 28·11 and 6·5 per cent. of the conductivity of purified copper. E. Wilson found the sp. resistance of commercial copper increases by adding 1·5–2·0 per cent. of silicon from $2·76 \times 10^{-6}$ to $3·3 \times 10^{-6}$ ohms, and the temp. coeff. falls from 0·0040–0·0030.

According to W. Hampe, alloys with over 3·47 per cent. of silicon become corroded on exposure to air; other observations were made by M. Philips, who found that hot water decomposes cuprosilicon liberating hydrogen, and forming copper silicate, Cu_2SiO_3 ; the Cu_2Si_2 alloys seem to be most readily attacked; the development of hydrogen begins between 46° and 65°, and is quite marked between 70° and 94°. The alloy with 12 per cent. of silicon increased in weight 7·6 per cent. after 48 hrs.' boiling with water. C. Combes found alloys with about 20 per cent. of silicon give with dry hydrogen chloride, copper and silicon chloroform. G. J. L. de Chalmot said that alloys with 39 per cent. of silicon react very slowly with sulphur at 200°–250°; and at 270°–280°, the copper of the alloy is converted into cupric and cuprous sulphides; similarly also with the 10–12 per cent. alloys; the silicon is set free. M. Philips said sulphuric acid or soln. of ammonium chloride liberates hydrogen at comparatively low temp. E. Vigouroux said that nitric acid readily dissolves alloys with 2·5 per cent. silicon, and black crystals remain when the 20 per cent. alloys are treated with this acid. W. Hampe said the 6 per cent. alloy is completely dissolved by the acid, and that with the 11·7 per cent. alloy small shining flecks are separated. G. J. L. de Chalmot said that aqua regia dissolves part of the copper from cuprosilicon. Molten mixtures of the alkali carbonates and nitrates readily decompose the alloy. E. Vigouroux found

that soln. of alkali hydroxide have little or no action on an alloy with 2.5 per cent. of silicon. P. Lebeau found the silicon is displaced from cuprosilicon when it is heated with many metals—silver, zinc, aluminium, and tin. P. Lebeau and J. Figueras obtained chromium silicide; E. Defacqz, molybdenum silicide. M. Philips describes the use of cuprosilicon for deoxidizing copper and bronze; and for toughening aluminium. G. Kroupa discusses the hardening of copper by cuprosilicon. E. Vigouroux found commercial cuprosilicons with 10, 13, and 15 per cent. of silicon; and C. J. L. Leffler analyzed one with 38.9 per cent. of copper, 54.23 per cent. of silicon, 6.71 per cent. of iron, and 0.12 per cent. of carbon.

J. J. Berzelius³ first noticed that silver alloys with silicon when the two elements are heated before the blowpipe, and he supposed **silver silicide** was formed because when the alloy was dissolved in acid, some silicic acid was formed. He obtained similar results when a mixture of charcoal and finely divided silver was strongly heated under a layer of glass containing only alkaline or earthy bases. F. Stromeyer said that under these conditions, silver unites with both carbon and silicon. J. S. Stas also noted that molten silver or silver vap. reduces silicates and silica *avec formation de silicate et de siliciure d'argent*. C. Winkler melted silver with 3, 10, and with 20 per cent. of silicon under cryolite, and obtained respectively silver-white, dirty grey, and grey-coloured alloys. G. J. L. de Chalmot obtained an argentosilicon alloy by heating sand, carbon, lime, and silver in an electric furnace. Some calcium was also present. F. Wöhler passed silicon hydride into a soln. of silver nitrate and obtained a precipitate which he regarded as a mixture of silver silicide and silver; G. Buchner regarded the precipitate as **silver nitratosilicide**, $\text{Ag}_3\text{Si}_4\text{AgNO}_3$, analogous to the precipitates obtained with arsine and stibine. E. Vigouroux passed silicon tetrachloride a number of times over molten silver but obtained only silver chloride, no silicide. H. N. Warren obtained an alloy by heating a mixture of silver, sodium, and potassium fluosilicate at a high temp. He concluded that silver unites with silicon only when the latter is *in statu nascendi*. J. Percy said that he could find no sign of combination when crystalline silicon is heated in contact with silver; nor did L. Kahlenberg and W. J. Trautmann observe any signs of combination. H. Moissan also noted that molten silver dissolves silicon and gives it up again on cooling. It therefore follows that the claims of F. Wöhler, H. N. Warren, G. J. L. de Chalmot, J. J. Berzelius, F. Stromeyer, and C. Winkler to have obtained alloys which contained silver silicide are invalid; *au contraire*, J. Percy, H. Moissan, and E. Vigouroux claimed that silicon and silver do not unite chemically, and they are probably correct. H. Moissan and F. Siemds measured the solubility of silicon in molten silver at different temp., and expressing the results in parts of silicon, per 100 parts of silver, found:

	970°	1180°	1250°	1470°
Solubility	9.22	14.89	19.26	41.46

The silicon is rejected as the soln. cools. The results are plotted in Fig. 8.

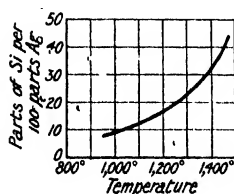

FIG. 8.—Solubility of Silicon in Molten Silver.

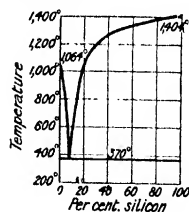

FIG. 9.—Fusion Curves of Au-Si Alloys.

G. Arrivaut found that the liquidus curve of the silicon-silver alloys has two branches, one of which starts from the m.p. of silver, and the other from the m.p.

of silicon, 1415° ; the two curves intersect at the eutectic temp., about 800° , at a point corresponding with about 5 per cent. of silicon (*vide* Fig. 9, 3, 22, 7). The solidus is a horizontal line passing through the eutectic, ranging from 0 to 90 per cent. silicon. No mixed crystals were formed. In the fusions containing 40–60 per cent. of silicon, a small white pearl is formed on the bluish-grey button of slightly oxidized silver. This is attributed to the increase in vol. of silicon on solidification; it contains 46 per cent. silicon and 94.85 per cent. silver. The subject was also studied by W. Manchot and co-workers.

C. Winkler⁴ obtained alloys of gold with 3 and with 10 per cent. of silicon. He said that the former is dirty yellow, and that the latter is yellowish-grey and brittle. H. N. Warren said that gold *in statu nascendi* unites with silicon much more readily than is the case with silver, and he claimed to have made gold silicide by heating gold and sodium with potassium fluosilicate at a bright red heat. E. Vigouroux could not obtain any evidence of the formation of a gold silicide ('di Capua found gold and silicon to be totally miscible when liquid; to be mutually insoluble in the solid state; and to form no compounds. The eutectic, Fig. 9, contains about 94 per cent. of gold, and solidifies at 370°).

§ 8. The Silicides of the Calcium Family

F. Wöhler¹ prepared calcium silicide by heating an intimate mixture of dry, warm, anhydrous calcium chloride, silicon, and sodium in a crucible brasqued with dry sodium chloride. The lead-grey crystalline regulus was very impure. Analyses varied from

Free Si	Combined Si	Ca	Mg	Na	Al	Fe
6.68-66.05	14.55-52.16	9.53-34.61	0.17-2.48	0.39-3.35	0.22-3.16	0.30-2.19

H. Moissan and W. Dilthey heated a mixture of equal parts of calcium oxide and silicon in a crucible of retort graphite in an electric arc furnace. The crucible was removed from the furnace as soon as the mass was melted in order to avoid forming calcium carbide and silicon carbide. The regulus contains some calcium carbide and silicate as impurities. The product is not satisfactory if an excess of silicon be used. G. J. L. de Chalmot made a calcium silicide by heating silica, calcium oxide, and carbon in an electric furnace; R. Frilley, G. Gin, L. Baraduc-Muller, and C. S. Bradley described somewhat similar processes. E. Jüngst and R. Mewes heated silicon with calcium chloride or fluoride in an electric furnace. T. Goldschmidt, and S. Herrmann heated calcium oxide or carbonate with silicon in a crucible at the temp. of molten cast-iron. The calcium oxide is partly reduced to form calcium silicide, and part forms a slag: $3\text{CaO} + 5\text{Si} = 2\text{CaSi}_2 + \text{CaSiO}_3$. The reaction can be satisfactorily conducted in an electric furnace, and calcium chloride or fluoride can be used as a flux. In order to avoid the formation of a silicate, La Compagnie Générale de l'Electrochimie employed calcium carbide in place of calcium oxide: $\text{CaC}_2 + 2\text{SiO}_2 + 2\text{C} = \text{CaSi}_2 + 4\text{CO}$; and $2\text{Si} + \text{CaO} + \text{C} = \text{CaSi}_2 + \text{CO}$. A. Barger heated calcium with silica in vacuo. *H. le Chatelier, and N. Caro mention the occurrence in commercial calcium carbide of crystals of what were considered to be calcium disilicide, CaSi_2 . None of these processes suffice to establish the existence of calcium silicide as a chemical individual. •

S. Tamaru prepared alloys of these two elements from calcium and silicon fused in an atm. of nitrogen. The crucibles of carbon or porcelain were lined with magnesia and tar, and then fired. The product always contained some calcium nitride, and some magnesium.

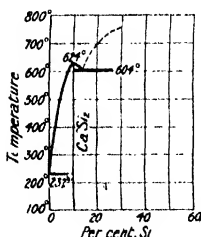

FIG. 10.—Portion of Equilibrium Diagram of Calcium and Silicon.

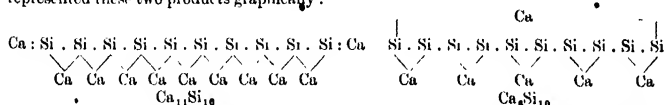

He found silicon is practically insoluble in calcium at 900°, but at 990° a reaction occurs. The equilibrium diagram is shown in Fig. 10. The evidence shows that probably calcium disilicide, CaSi_2 , is formed, and may be another silicide. L. Wöhler and F. Müller could not make this compound directly, but obtained it by heating Ca_3Si_2 in a stream of hydrogen at 1000°-1010°; if an excess of silicon is present, this reacts with the calcium hydride to form more calcium disilicide. L. Wöhler and O. Bock obtained it from its elements at 1000°-1100° in hydrogen. The heat of formation is $\text{Ca} + 2\text{Si} = \text{CaSi}_2 + 208.7 \text{ Cals.}$

L. Wöhler and F. Müller also made calcium monosilicide, CaSi , or Ca_3Si_2 , free from the disilicide, by heating a mixture of calcium and silicon in atomic proportions or with excess of silicon up to 100 per cent. in a magnesia boat in an atm. of carbon dioxide at 1050°. After 15 secs., a violent reaction takes

place and the mass becomes incandescent. It must then be cooled rapidly. The mass breaks up readily into small, lustrous, metallic leaflets and larger crystals. L. Wöhler and O. Bock made it from its elements at 1000° – 1050° in an atm. of carbon dioxide. The density of the substance, containing a small proportion of uncombined silicon, is 2.346. By dil. acids it is attacked readily with the evolution of a spontaneously inflammable silicon hydride and the formation of hydrated silica; it is only slowly attacked by conc. acids, with evolution of hydrogen and by cold water; more readily by warm water and by dil. ammonia. By contrast, the disilicide dissolves in hydrochloric acid with formation of yellow silicone and without production of spontaneously inflammable silicon hydride. When, in the preparation of the substance, so large an excess of silicon is used as to prevent the necessary rise in temp. during the reaction, a mixture of mono- and di-silicides is formed. From this it was concluded that the monosilicide is formed endothermically from the disilicide. The heat of formation is $2\text{Ca} + 2\text{Si} = \text{Ca}_2\text{Si}_2 + 166.3 \text{ Cals.}$, or $\text{CaSi}_2 + \text{Ca} = \text{Ca}_2\text{Si}_2 - 43 \text{ Cals.}$

R. Frilley obtained no clear evidence of the formation of definite compounds from the sp. gr. curve of the alloys. L. Hackspill made the disilicide by heating to 1000° in vacuo a compressed mixture of 6 grms. of silicon and 4 grms. of calcium filings. O. Hönigschmid said that this silicide is always produced when calcium is heated with an excess of silicon. P. Formhals, and A. Kolb found that when the two elements are heated in the proportions required for CaSi_2 , some silicon always remains uncombined, and a constant product is not obtained. R. Frilley said that when calcium oxide is reduced by silicon in the presence of carbon, calcium carbide is first formed, and this reacts with the silicon, forming calcium silicide. The reaction between ferrosilicon and calcium carbide is reversible. He also found that the calcium disilicide is obtained when many of the calcium-silicon alloys are digested with a boiling dil. soln. of sodium hydroxide. L. Hackspill claimed to have made needle-like crystals, calcium ditritasilicide, Ca_3Si_2 , by heating silicon with a large excess of calcium, say 1 : 4. The sp. gr. was 1.64 at 14° . L. Wöhler and F. Muller obtained it from its elements at 1000° ; they gave 166.3 for the heat of formation, and said that it yields spontaneously inflammable silicon hydride when treated with hydrochloric acid. O. Hönigschmid obtained a similar product. R. Frilley obtained no definite evidence of the individuality of this substance.

A. Kolb, and R. Formhals reported the formation of a silicide, $\text{Ca}_{11}\text{Si}_{10}$, or $\text{Ca}_{12}\text{Si}_{10}$, by the action of an excess of calcium on silicon, say 10 : 3. They also reported $\text{Ca}_4\text{Si}_{10}$ to be formed when calcium is heated with an excess of silicon. The analyses of this substance do not exclude the possibility that impure calcium disilicide is in question. R. Formhals represented these two products graphically:

The formulæ, however, have little meaning so long as their existence as chemical individuals is in doubt.

The calcium-silicon alloy made by H. Moissan and W. Dilthey is a grey, crystalline mass with a sp. gr. approximating 2.5; and with a hardness like that of quartz. F. Wöhler's alloy decomposed on exposure to air, forming plates with a metallic lustre and appearance, and it decomposed under water. H. Moissan and W. Dilthey's alloy was fairly stable towards water, and it was decomposed but slowly by cold water. G. Tammann studied the electrode potential and chemical properties of the calcium-silicon alloys. S. Tamaru said that finely divided alloys with 60–91 per cent. of silicon are scarcely affected by water; while those with 38–52 per cent. are attacked with the development of hydrogen. F. Wöhler's alloy was not attacked by heating it to redness in steam. H. Moissan and W. Dil-

they's alloy is not affected when heated to redness in hydrogen; it is superficially oxidized when heated in air; and it is incompletely oxidized when heated in oxygen. It readily burns in fluorine gas, forming silicon and calcium fluorides; chlorine, bromine, and iodine attack it at a dull red heat. F. Wöhler's alloy with conc. hydrochloric acid gives off hydrogen copiously; dil. sulphuric acid, acetic acid, and hydrofluoric acid behave similarly—with the last-named acid, the silicon is rapidly bleached and dissolved; with dil. hydrochloric acid, hydrogen is less copiously evolved, and translucent, lustrous plates are formed. When the plates are washed, and dried over sulphuric acid in vacuo, they often ignite when air is introduced, burning to a mixture of silica and silicon. H. Moissan and W. Dilthey obtained silicon-acetylene, Si_2H_2 , by treatment with dil. hydrochloric acid; with conc. sulphuric acid, gas was feebly evolved; conc. or fuming nitric acid oxidizes the alloy very slowly. According to L. Wöhler and O. Bock, the disilicide in nitrogen at 900° – 1100° forms CaSiN_2 ; and CaSi_2N_2 . S. Tamaru found that alloys with 60–91 per cent. of silicon are but slowly attacked by dil. acetic, oxalic, or tartaric acid, and likewise with dil. hydrochloric, nitric, or sulphuric acid, giving off hydrogen and spontaneously inflammable silicon hydride; alloys with 38–52 per cent. silicon are rapidly attacked by dil. acetic, oxalic, tartaric, hydrochloric, nitric, or sulphuric acid, giving off a spontaneously inflammable gas, and forming a white powder which dissolves in alkali-lye with the evolution of hydrogen—*vide* silicone. E. Donath and A. Lissner said that sulphur has no action at a red heat, while hydrogen sulphide attacks the alloy superficially. F. Wöhler found that with an aq. soln. of sulphur dioxide and a little hydrochloric acid, no gas is evolved, but the alloy is transformed into reddish-brown copper-coloured plates; the brown liquid becomes turbid and there is a separation of sulphur. When the residue which remains when the liquid is poured off is dried in vacuo, and extracted with carbon disulphide, a pale greenish-brown powder remains—*vide* silicone.

This powder smells of hydrogen sulphide, and when heated detonates; if very gradually heated, hydrogen sulphide is given off, and when no more gas is evolved, the product yields more hydrogen sulphide when treated with water. Ammonia converts the substance into a white mixture of silica and silicon, and hydrogen is at the same time evolved. Analyses correspond roughly with $\text{H}_2\text{Si}_2\text{N}_2$.

A vermilion-red product is formed with selenium dioxide and a little hydrochloric acid; and tellurium dioxide under similar conditions forms a greyish-black product. A. Geuther, and C. Eichel found that when calcium silicide is heated in nitrogen, calcium nitride is formed and silicon separates out. According to H. Moissan and W. Dilthey, when the calcium-silicon alloy is heated with carbon, it forms calcium carbide, etc.; it is rapidly dissolved by molten aluminium. The alloy containing some aluminium was found by R. Frilley to be attacked more vigorously the greater the proportion of aluminium. When the carbon-silicon alloy is dissolved by molten iron, it forms iron silicide. Soln. of alkali hydroxide readily decompose the alloy, with the evolution of hydrogen. S. Tamaru said that silicon-calcium alloys are not attacked by alkalis and ammonia. L. Wöhler and O. Bock found that the absorption of nitrogen by heated calcium silicon alloys is accelerated by calcium chloride and fluoride, while the carbonate and sulphate make very little difference. The alloys form ammonia or its equivalent when treated with water, hydrochloric acid, conc. alkali-lye, or fused alkalis. They showed that both *calcium silicocyanamide*, CaSiN_2 , and *calcium silocyanide*, $\text{Ca}(\text{SiN})_2$, are formed. E. Donath and A. Lissner found that liquid ammonia and organic solvents have no action. S. Tamaru found that molten calcium-silicon alloys readily attack porcelain. Calcium-silicon alloy is a strong reducing agent, and, according to C. S. Bradley, and T. Goldschmidt, can be used for removing sulphur and phosphorus from steel; and, according to W. S. Anderson, as a deoxidizing agent for iron and steel.

C. S. Bradley prepared **strontium disilicide**, SrSi_2 , by melting together carbon,

silicon, and strontium carbonate or oxide in an electric furnace; E. Jüngst and R. Mewes made it by heating silicon with strontium chloride or fluoride in an electric furnace; T. Goldschmidt, by heating strontia and silicon in an electric furnace; and R. Frilley, by melting a mixture of strontium carbide, silica, and aluminium in an electric furnace. The existence of this compound as a chemical individual has not been established. The alloy is white and crystalline. C. S. Bradley found that it decomposes water with the evolution of hydrogen; and with dil. hydrochloric acid, it gives off a mixture of hydrogen and silicon tetrahydride. It is a strong reducing agent. C. S. Bradley made what he regarded as **barium disilicide**, BaSi_2 , by a process analogous to that employed for the calcium and strontium disilicides. The product behaved in a similar way. T. Goldschmidt obtained a barium silicide, BaSi_2 , by reducing barium oxide with silicon, but none was obtained by L. Kahlenberg and W. J. Trautmann. O. Hönigschmid said that barium disilicide is formed when barium is heated with an excess of silicon, and R. Frilley added that the compound is more difficult to make than calcium disilicide. T. Goldschmidt made it by heating barium and silicon as in the case of the corresponding calcium compound. R. Frilley made it by heating a mixture of silica and barium carbide with either carbon or, better, with aluminium. According to P. Askenasy and C. Ponnaz, barium peroxide and silicon react very violently when the reaction is initiated by means of a fuse. By using coarsely-powdered barium peroxide (50 parts) and silicon (15 parts), a barium silicide with 30 per cent. of barium is obtained. The mixture (with less silicon and a little sodium peroxide) may also be used to fuse iron or copper, or powdered ferro-silicon or titanium silicide may be used in place of silicon. E. Jüngst and R. Mewes likewise prepared what they regarded as **barium hemisilicide**, Ba_2Si , by the process which they employed for strontium silicide. The steel-grey mass is decomposed by water and dil. hydrochloric acid, as in the case of the other alkaline earth silicides. According to R. Frilley, it is not attacked by cold chlorine, bromine, or iodine. Soln. of bromine or iodine dissolve it without the development of any gas; hydrofluoric and hydrochloric acids attack it vigorously giving off a spontaneously inflammable gas. Nitric, sulphuric, and phosphoric acids behave similarly but less vigorously. Acetic acid does not give a spontaneously inflammable gas. A soln. of chromic acid behaves like a soln. of bromine; and aq. ammonia has no action.

§ 9. The Silicides of the Magnesium-Zinc Family

Silicon and beryllium are readily alloyed, and H. Debray¹ said alloys with up to 20 per cent. of silicon are hard and brittle, and can be readily polished. A. Ditte said that up to 1891, beryllium had not been obtained free from silicon. According to P. Lebeau, when beryllia is reduced by silicon in the electric furnace, the resulting beryllium silicide is contaminated with silicon carbide. No definite compound has been isolated.

A number of magnesium silicides has been reported, but the existence of only **magnesium hemisilicide**, Mg_2Si , has claims to recognition; the others are probably mixtures of this silicide with magnesium or silicon; and, according to O. Högnschmid,² this silicide is always formed when the magnesium is heated with silicon and when either constituent is present in excess. T. W. C. Martius noted the occurrence of magnesium silicide in a slag obtained in the preparation of magnesium. F. Wöhler made the alloy by melting together magnesium chloride, sodium, and sodium fluosilicate. Fluorspar can be used as a flux. C. Winkler melted sodium fluosilicate with magnesium, using sodium chloride as a flux; P. Lebeau and R. Bossuet employed a similar process for alloys with 0-45 per cent. of silicon; and for alloys with more silicon, they fused magnesium filings, crystalline silicon, and a small quantity of potassium fluosilicate. C. Winkler also obtained what he regarded as *magnesium tripentasilicide*, Mg_3Si_3 , and the hemisilicide, Mg_2Si , by heating the constituent elements in a stream of hydrogen; but not by melting the two elements under sodium chloride as a flux. E. Vigouroux, and H. Moissan and S. Smiles also obtained the alloys by melting the two elements in the electric furnace. J. Parkinson, and T. L. Phipson first observed the formation of magnesium silicides in the reduction of silica by magnesium. C. Winkler, and L. Gattermann and co-workers heated silica with magnesium: $SiO_2 + 4Mg = 2MgO + Mg_2Si$. The preparation of magnesium silicide best suited for making the silicon hydrides (*q.v.*) has been investigated by A. Geuther, H. Moissan and S. Smiles, and A. Stock and C. Somiesky. The last-named workers made the silicide by heating calcined silicic acid with twice its weight of commercial magnesium powder at as low a temp. as possible. The product is best if the silica contains less than one per cent. of alkali as impurity; silica free from alkalies reacts with magnesium too vigorously, producing a high temp. The product is not then readily attacked by acids. M. L. V. Gayler studied the solubility of the hemisilicide in molten aluminium.

A. Stock and C. Somiesky made magnesium silicide by placing 100 grms. of a mixture of calcined precipitated silica with twice its weight of commercial powdered magnesium in an iron crucible of a litre capacity. The crucible was placed in a vessel of cold water. The reaction was started by a fusee and was over in a few moments; and a stream of hydrogen (washed in sulphuric acid) was sent from a bomb through a tube in the perforated lid of the crucible so that the product cools for half an hour in an atm. of hydrogen. The mass was then broken into coarse fragments not over 0.5 mm. diameter, and the dust which passed through a millimetre-mesh sieve was rejected. The magnesium silicide so prepared has a bluish colour and is markedly crystalline. R. Schwarz and E. Konrad recommended working in an atm. of hydrogen, and mechanically separating the crystals of the silicide from the mixture. The crude product was freed from magnesium by the action of ethyl bromide and anhydrous ether. The purified material is a steel-blue crystalline powder which contains traces of amorphous silicon and iron silicide.

H. N. Warren prepared silicon-magnesium alloys by the action of magnesium on silicon fluoride; K. Seubert and A. Schmidt, by the action of magnesium on silicon chloride; and E. Jüngst and R. Mewes, by the action of silicon on magnesium halides in an electric furnace. T. Goldschmidt made the alloy from magnesia and silicon as in the case of calcium-silicon alloys. R. Vogel made a series of alloys directly from the elements heated in carbon tubes in an atm. of hydrogen; he found

that the molten alloys strongly attack porcelain and magnesia vessels. The f.p. curve, Fig. 11, falls rapidly from the f.p. of silicon to a eutectic at 950° and 42 per cent. of magnesium; it then rises to a maximum at 1102° and 63·2 per cent. of magnesium corresponding with Mg_2Si ; there is a second eutectic at 645° and 96 per cent. of magnesium. No solid soln. were observed. There is here no evidence of F. Wöhler's *magnesium tritritasilicide*, Mg_3Si_3 , or of C. Winkler's *tripentasilicide*. According to P. Lebeau and R. Bossuet, under the microscope, polished surfaces (i) of an alloy containing 0·38 per cent. of silicon, show grains of magnesium surrounded by a eutectic, but no crystals of the silicide; (ii) in alloys containing 6-8 per cent. of silicon, well-defined crystals of the silicide appear in the midst of a eutectic very rich in magnesium; (iii) that an alloy containing 40 per cent. of silicon contains that element mainly as crystals of the free silicon; and (iv) crystals of free silicon in alloys containing silicide and a eutectic differing from the former and containing more than 50 per cent. of that element. The pure silicide cannot be isolated by treating the alloys with any aq. reagent, owing to the decomposing action of water, but the magnesium is dissolved away from an alloy containing 25 per cent. of silicon by means of ethyl iodide and ether, leaving brilliant, slate-blue, octahedral crystals of **magnesium hemisilicide**, the analysis of which corresponds accurately with the formula Mg_2Si . P. Lebeau and R. Bossuet found that the glistening octahedral crystals of magnesium hemisilicide are slate-blue in reflected light, and in thin layers, by reflected light, they have a reddish tinge. E. A. Owen and G. D. Preston found that the X-radiogram corresponds with a face-centred cube lattice of silicon atoms of side 6·391 Å., symmetrically intermeshed with a simple cube lattice of magnesium atoms of side 3·19 Å. There are eight magnesium atoms situated within each face-centred cube of silicon atoms, dividing the four diagonals in the ratio 1 : 3 and 3 : 1. The sp. gr. from X-ray data is 1·95+0·05 grms. per c.c. The magnesium atoms are separated by the same distance as in the pure metal; and the sum of the so-called radii of the silicon and magnesium atoms is equal to the distance between these atoms in the compound. The sp. gr. is about 2; and the hardness between that of fluor spar and orthoclase. The m.p., said R. Vogel, is 1102°. A. M. Portevin and P. Chenevard studied the expansion which occurs on heating magnesium-silicon alloys, and found a contraction at about 350° due to the gradual dissolution of magnesium hemisilicide, and conversely an expansion on cooling below that temp. P. Schübel gave 0·2320 for the sp. ht. of Mg_2Si between 18° and 298°; and 0·2445 between 18° and 630°. The alloys are not attacked by atm. air. P. Lebeau and R. Bossuet found that the alloys are easily oxidized and give sparks by friction against a hard substance in air. When heated between 1100° and 1200° in hydrogen or in vacuo, the compound is resolved into its elements. The heat developed by the vigorous combustion which occurs when heated in oxygen is sufficient to fuse the magnesium silicate which is formed. The compound slowly decomposes water at ordinary temp. giving hydrogen, but no silicon hydride. Cold hydrochloric acid attacks the alloy vigorously, forming hydrogen and spontaneously inflammable silicon hydride. P. Lebeau said the gas contains silicomethane, silicoethane, and a little silicoethene. For the solid product, *vide* silane.

According to A. Geuther, when magnesium silicide is treated with hydrofluoric acid, hydrogen is evolved. R. Vogel said that the alloy is slowly attacked by conc. sulphuric or nitric acid, but the attack is rapid with the dil. acids, and hydrogen

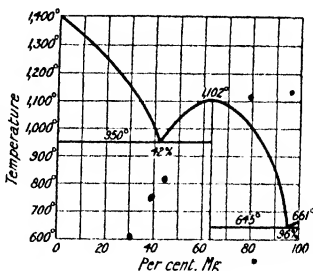

FIG. 11.—Equilibrium Diagram of Magnesium-Silicon Alloys.

is evolved. P. Lebeau and R. Bossuet found the alloy to be a strong reducing agent. A. Geuther found that magnesium nitride and free silicon are formed by heating the alloy at a high temp. in nitrogen, and that a cold aq. soln. of ammonium chloride acts slowly on the alloy: $2Mg_2Si + 8NH_4Cl + 3H_2O = 4MgCl_2 + Si_2H_2O_3 + 8NH_3 + 6H_2$. The alloy is not attacked by a cold or hot aq. soln. of potassium hydroxide. G. Tammann studied the electrode potential and chemical properties of the magnesium-silicon alloys.

No zinc silicide has been isolated. According to H. St. C. Deville and H. Caron,³ silicon dissolves in molten zinc, and all but a little separates from the soln. during solidification. Similar results were obtained by C. Winkler, and E. Vigouroux. W. Manchot and W. Funk studied this subject. H. Moissan and F. Siemens found the solubility increases rapidly with rise of temp.; and that the solubility in 100 parts of zinc, is:

Solubility	600°	650°	730°	800°	850°
	0.06	0.15	0.57	0.92	1.62

W. Sander and K. L. Meissner studied the ternary system, Zn-Mg-Si. W. Frankel found that when a mixture of zinc sulphide and carbon is heated in a quartz vessel to 1300°-1400° in an atm. of nitrogen, a volatile product is obtained, containing zinc, carbon, and sulphur, which reacts with the silica of the enclosing vessel. The product is also volatile, and corresponds approximately with the composition zinc sulphosilicide, ZnSSi. Using a carbon lining to the tube, the vapour nevertheless penetrates to the quartz, and introduces silicon into the mixture. The same compound is also obtained by heating zinc sulphide to 1300° with silicon. It condenses to hard, brown crusts. With acids the sulphur is evolved quantitatively as hydrogen sulphide, and with aq. alkalies, hydrogen is evolved. It may be polished like a metal, and is microscopically homogeneous. The electrical conductivity is less than that of silicon.

No cadmium silicide has been prepared, nor has the action of silicon on cadmium been studied. C. Winkler did not observe any signs of the formation of a mercury silicide when mercury and silicon are heated in a sealed tube to 100° or to 300°; nor do the two elements unite when allowed to stand in contact under a dil. soln. of sodium hydroxide. He utilized this property to separate aluminium from silicon. H. N. Warren obtained no silicide by the action of mercury on heated potassium fluosilicate. A little silicon amalgam is formed when an alcoholic soln. of silicon fluoride is electrolyzed with a mercury cathode. Silicon remains when the mercury is distilled off. L. Kahlenberg and W. J. Trautmann observed no formation of an alloy when mercuric oxide is reduced by silicon at a high temp.

§ 10. The Silicides of the Aluminium and Rare Earth Families

For boron silicide, *vide* silicon boride. No aluminium silicide has been isolated; *dans tous les cas*, said E. Vigouroux, *il y a simplement dissolution du silicon dans l'aluminium*; if a third element be present, however, a complex silicide may be formed. H. St. C. Deville¹ stated that:

Any siliceous material in contact with aluminium at a high temp. is always decomposed; and if the metal is in excess there is formed an alloy or a combination of silicon and aluminium in which the two bodies may be united in almost any proportions. Glass, clay, and the earth of crucibles act in this way. However, aluminium may be melted in glassware or earthen crucibles without the least contamination of the metal if there is no contact between the metal and the material; the aluminium will not wet the crucible if put into it alone. However, the moment that a flux facilitates immediate contact (even sodium chloride does thus), the reaction begins to take place, and the metal obtained is always more or less siliceous. It is for this reason that I have prescribed in melting aluminium not to add any kind of flux, even when the flux would not be attacked by the metal.

H. St. C. Deville obtained aluminium charged with 10.3 per cent. of silicon. In preparing aluminium, F. Wöhler obtained globules of what he regarded as aluminium silicide containing crystals of silicon, and which, when treated with acids, gave hydrogen and silicon hydride. F. Wöhler treated potassium fluosilicate with aluminium, and obtained an alloy with about 70 per cent. of silicon. C. F. Rammeßberg reduced cryolite with sodium in a porcelain crucible, and obtained an alloy which when treated with hydrochloric acid showed the presence of combined and free silicon. The former changed partly into silica, and partly into gaseous silicon tetrahydride; while the latter remained as a black residue of graphitoidal silicon.

Silicon as	SiO ₂	SiH ₄	Free
Per cent.	1.85 9.55	0.58 0.74	0.12 0.17

C. Winkler obtained an alloy with 69.34 per cent. of silicon by reducing a mixture of cryolite and quartz with aluminium. J. H. J. Dagger described the production of the alloy by reducing the oxides with carbon in the electric furnace. A. Minet prepared the alloy by the electrolysis of a fused mixture of sodium chloride and sodium fluoaluminate mixed with alumina and silica. R. Frilley used a similar process; and he also electrolyzed a fused mixture of sodium and potassium fluorides, silica, and cryolite; and also added silica to the fused mixture employed for preparing aluminium. E. Donath and A. Lissner dissolved calcium silicide in molten aluminium, and found that some aluminium silicide was formed which gave spontaneously inflammable silicon hydride when treated with an acid. E. Kohn-Abrest found that when aluminium is heated in a porcelain boat at 1100° in a vacuum the metal is rapidly volatilized at first, but, after some hours, the loss in weight from this cause becomes negligible. After prolonged heating, the residue is found to be coated with a yellow film, consisting of an alloy of aluminium and silicon. The same results are obtained when boats of pure graphite are employed, but only when these are contained in a porcelain tube. The conclusion drawn is that aluminium

vap. attacks the porcelain, liberating silicon, which is absorbed by the molten aluminium. The porcelain tubes employed are found to be coated internally with a black, crystalline deposit, having the composition *aluminium hemisilicide*, Al_2Si , is said to have been isolated. R. Frilley, L. D. Hooper, and E. Viel obtained aluminium hemisilicide by heating china clay in an arc furnace. T. Goldschmidt reduced silica by aluminium in the thermite process, although E. Weston and H. R. Ellis could not obtain a silicide by reducing silica by powdered aluminium; R. Frilley reduced silica by aluminium in the electric furnace and obtained an alloy with 30-36 per cent. silicon. L. Baraduc-Muller heated, to 1700° , a mixture of one mol. of alumina with 3 mols. of silicon carbide along with lime and magnesia as fluxes, and obtained aluminium-silicon alloys. J. J. Curran examined the influence of sodium on these alloys; M. L. V. Gayler and co-workers, alloys of aluminium, magnesium, copper, and silicon; and W. Sander and K. L. Meissner, alloys of magnesium, zinc, aluminium, and silicon. A binary alloy of aluminium and about 10 per cent. of silicon is called *silumin*. It was studied by G. Masing. T. B. L. Cain, and Z. Jeffries made some observations on these alloys.

For a time, it was thought that the alloy prepared by H. St. C. Deville by the action of silicon tetrachloride on aluminium at a red heat was *aluminium hemisilicide*, Al_2Si , and that the specimen prepared by C. Winkler was *aluminium trihemisilicide*, Al_2Si_3 , but the conclusion was based merely on the analyses. The observation of F. Wöhler and H. Buff that the alloy furnished silicon hydride when treated with hydrochloric acid supported the view that a true compound is formed; and this is confirmed by C. F. Rammelsberg's observation—*vide supra*. E. Vigouroux, and R. Frilley failed in the attempt to make aluminium and silicon unite directly; on the other hand, added E. Vigouroux, if the materials are impure, or if metallic oxides be present, *silicoaluminides* of iron, nickel, cobalt, chromium, molybdenum,

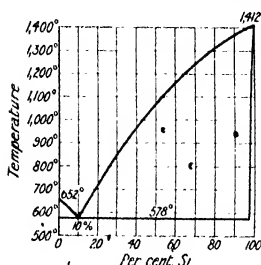

FIG. 12. —Equilibrium Diagram of Aluminium-Silicon Alloys.

tungsten, uranium, manganese, vanadium, and titanium are readily produced. W. Fränkel found that molten silicon and aluminium are miscible in all proportions, but they do not enter into chemical combination. The f.p. curve consists of two branches, Fig. 12; the eutectic mixture contains about 10 per cent. of silicon, and solidifies at 576° . Whether mixed crystals are formed could not be satisfactorily determined; if they exist, those rich in aluminium do not contain more than 0.5 per cent. of silicon, and those rich in the latter element not more than 2 per cent. of aluminium. A. M. Portevin studied the structure of the eutectic; and the changes in vol. on cooling. W. Manchot and co-workers measured the solubility of silicon in aluminium; E. H. Dix and A. J. Lyon, and H. Schirmeister, the tensile strength of the alloys. C. E. Roberts confirmed the observations of W. Fränkel; and H. Sutton described these alloys. J. Czochralsky called an alloy with 11-14 per cent. silicon *silumin* and *alpac*; these other alloys have been described by J. D. Edwards and R. S. Archer, L. Guillet, J. J. Curran, R. E. Starch, etc. According to R. Frilley, alloys with up to 10 per cent. of silicon are a little greyer than aluminium alone. The alloys work well. Alloys with 10-20 per cent. of silicon are lustrous and crystalline, more fusible than aluminium alone—*vide* Fig. 12. The alloys with up to 15 per cent. of silicon can be forged. Alloys with 20-38 per cent. of silicon are markedly crystalline, and they readily fracture; they have a bluish tinge. Crystals of silicon appear with alloys with over 38 per cent. of that element. Alloys with 40-55 per cent. of silicon have a matrix of anastomosed crystals. Alloys with over 55 per cent. of silicon look like *silicon fondu*—fused silicon. E. Wetzel found aluminium may have 0.5 per cent. of silicon

in solid soln. at ordinary temp., and one per cent. at 550°. E. C. Bain studied the X-radiograms of the alloys. The sp. gr. of the alloys are :

Per cent. Si	10	20	30	47.5	64	85.2	9.65
Sp. gr.	2.52	2.50	2.45	2.44	2.40	2.35	2.37

The sp. gr. curve shows no singularities, and there is no evidence of the formation of definite silicides when silicon and aluminium are fused together ; D. R. Tullis also studied the sp. gr. of these alloys. The physical properties have been studied by J. D. Edwards and co-workers, D. Basch and M. F. Sayre, L. Guillet, etc. The alloys are completely soluble in fused alkali hydroxides and carbonates, and in hot conc. soln. of alkali hydroxides. Hydrochloric acid attacks the alloys vigorously, and a deposit analogous to silicone is formed (*q.v.*) ; hydrofluoric acid behaves like hydrochloric acid ; sulphuric acid readily attacks the alloy ; nitric acid, hot or cold, attacks the alloys very slowly ; and a mixture of nitric and hydrofluoric acids dissolves the alloys vigorously.

R. Frilley melted in an electric furnace a mixture of calcium silicide with aluminium using cryolite or fluorspar as a flux. He thus obtained crystalline alloys corresponding with calcium trisilicodialuminide, CaAl_2Si_3 , and calcium trisilicotetraluminide, CaAl_4Si_3 . Hydrofluoric or hydrochloric acid attacks the alloys vigorously, developing spontaneously inflammable silicon hydride, and leaving as a residue graphitic silicon. V. Fuss, and R. Frilley likewise obtained alloys representing magnesium silicoaluminide. A. M. Portevin and P. Chevenard studied the vol. changes with alloys of magnesium, aluminium and silicon. V. Fuss, and H. E. Dix and A. J. Lyon studied the physical properties of the ternary alloys silicon-copper-aluminium ; S. Daniels, Al-Si-Mg alloys ; V. Fuss, the ternary alloys Si-Al-Mg, Si-Al-Fe, and Si-Al-Ni ; and W. Sander and K. L. Meissner, the ternary alloys Zn-Mg-Si ; Al-Mg-Si ; and Al-Zn-Si ; and quaternary alloys Si-Al-Zn-Mg. L. Guillet investigated the binary, ternary, and quaternary alloys of aluminium, copper, silicon, and magnesium.

S. Tamaru² found that molten thallium and silicon are *praktisch miteinander nicht mischbar*. This is shown by the f.p. curve, Fig. 13. There is no sign of the formation of a definite thallium silicide. F. Ullik electrolyzed cerium fluoride and obtained a black powder which was regarded as cerium silicide because the analysis corresponded with CeSi . It was not investigated further. J. Sterba prepared cerium disilicide, CeSi_2 , by heating cerium oxide and silicon in an electric furnace. It forms small crystals with a steely lustre ; the density at 17° is 5.67. It is only slowly acted on by water ; hydrogen is without action on it. Fluorine acts in the cold on it, chlorine, bromine, or iodine only after heating. When heated to redness, it burns in oxygen with a vivid incandescence, and when heated in boiling sulphur or selenium, it burns. Hydrogen chloride acts on it at a red heat. Soln. of hydrochloric and hydrofluoric acids attack it with evolution of hydrogen. Hydrogen sulphide and water are attacked at a red heat. Aq. soln. of alkali hydroxides and ammonia do not react with it in the cold. Only a portion of the thermal diagram has been explored by L. Guillet, and R. Vogel. This is indicated in Fig. 12, 5, 38, 10. There is a maximum on the curve corresponding with cerium silicide, CeSi , of m.p. 1500°. This forms an eutectic with silicon. The eutectic is at 1256° with 46 per cent. Si.

§ 11. The Silicides of the Titanium and Tin Families

For the carbon silicides, vide silicon carbides. L. Levy¹ treated titanium tetrachloride with silicon and obtained arborescent crystals of titanium hemisilicide, Ti_2Si , which were not closer investigated. H. Moissan obtained a silicide by heating a mixture of silicon and titanic oxide in the electric arc furnace. L. Baraduc-Muller heated a mixture of titanic oxide, silicon carbide, and carbon with a mixture of lime and magnesia as a flux. P. Askenasy and C. Ponnaz obtained what they regarded as titanium trihemisilicide, Ti_3Si_3 , by heating the constituents in an electric furnace. O. Höning Schmid made titanium disilicide, $TiSi_2$, by heating in a fireclay crucible a mixture of 200 grms. powdered aluminium, 250 grms. of sulphur; 180 grms. of fine sand, and either 15 grms. of titanic oxide or 40 grms. of potassium fluotitanate, covering all with a thin layer of powdered magnesium, and igniting with a thermite pastille. Titanium disilicide crystallizes in small, iron-grey, tetragonal pyramids, having a hardness of 4-5 and a sp. gr. 4.02 at 22°. It oxidizes with difficulty, but burns in chlorine at below a red heat. It is insoluble in mineral acids excepting hydrofluoric acid, but dissolves slowly in 10 per cent. potassium hydroxide soln. Fused potassium hydroxide reacts vigorously with it at a red heat, but potassium hydrogen sulphate is without action under these conditions. H. Moissan said titanium silicide is as hard as the diamond; and G. Gin recommended its use for cutting and polishing gem-stones. P. Askenasy and C. Ponnaz's product behaves like silicon towards barium dioxide—vide barium silicide.

E. Wedekind² prepared crystals of zirconium silicide by reducing zirconia with silicon in the electric furnace. O. Höning Schmid prepared zirconium disilicide, $ZrSi_2$, by a method similar to that employed for titanium disilicide—vide supra—and also by heating a mixture of potassium fluozirconate and fluosilicate and aluminium. The compound crystallizes in small, iron-grey, rhombic columns with

a metallic lustre, a hardness approximating to that of felspar, and a sp. gr. of 4.88 at 22°. It is stable in the air, but burns vigorously when its powder is heated on platinum foil. It is not attacked by mineral acids with the exception of hydrofluoric acid, which readily dissolves it, hydrogen being evolved; a 10 per cent. potassium or sodium hydroxide soln. is without action on it, as also is potassium hydrogen sulphate at a red heat. It is decomposed by fusion with potassium hydroxide. According to R. Wedekind, zirconium silicide is readily obtained in the colloidal state.

E. Wedekind and K. Fetzner³ found that a mixture of thorium and silicon in the electric arc furnace gave a silicide which was washed with hydrochloric acid, and then with a 2 per cent. soln. of potassium hydroxide to remove the uncombined silicon. The m.p. is very high, and the product is decomposed by conc. alkali-lye. O. Hönigschmid prepared **thorium disilicide**, ThSi_2 , by heating in an electric furnace a mixture of thorium and silicon; a mixture of aluminium, silicon, and thorium; or by the interaction of a mixture of the double fluoride of thorium and potassium, potassium silicofluoride, and aluminium at 1200°, and purified the products from free aluminium and silicon by treatment with potassium carbonate soln. It forms quadratic plates resembling graphite in colour, has a sp. gr. 7.96 at 16°, and when heated combines readily with the halogens, oxygen, sulphur, selenium, or hydrogen chloride, but it is not attacked by hydrogen at a red heat. It is soluble in aq. soln. of the mineral acids, is not attacked by soln. of the alkali hydroxides, but is decomposed on fusion with sodium or potassium hydroxides. For analysis, the compound was dissolved in aqua regia or in a mixture of hydrofluoric and nitric acids, or decomposed by fusing with moist sodium hydroxide.

J. J. Berzelius⁴ observed that when tin and silicon are melted before the blowpipe, a ductile alloy is formed, which, when treated with acids, produces some silica. C. Winkler said that silicon can be alloyed with tin. Alloys with 2-3 per cent. silicon were said to be white, and not very malleable; alloys with 10 per cent. silicon were greyish-white and brittle. Warm hydrochloric acid dissolves the tin, and leaves the silicon partly free and partly as silica. E. Vigouroux⁵ said that alloys of tin are only mixtures, and contain no tin silicide. H. N. Warren obtained crystals of silicon by dissolving the amorphous element in molten tin, and cooling the soln. S. Tamaru found that molten silicon and tin are miscible in all proportions, and, on cooling, pure silicon separates, the eutectic being practically pure tin. The f.p. curve, Fig. 14, falls very slowly until about 80 per cent. tin is reached, and then very rapidly. L. Kahlenberg and W. J. Trautmann observed no formation of tin silicide.

As in the case of tin, J. J. Berzelius found that silicon dissolves in lead melted before the blowpipe, and forms a malleable alloy or compound. H. N. Warren also said that a brittle **lead silicide** is formed when lead oxide is heated with silicon. H. St. C. Deville and H. Caron could not get the two elements to form an alloy. C. Winkler could not get an alloy at a red heat when the two elements were heated under a layer of cryolite. The silicon floated on the molten lead. He observed no signs of the formation of a lead silicide. A similar observation was made by L. Kahlenberg and W. J. Trautmann. E. Vigouroux observed that no dissolution of silicon in molten lead occurs at 1200°. H. Moissan and F. Siemens found that silicon commences to dissolve appreciably in lead at about 1250°, and that the solubility in 100 parts of lead is as follows:

	1250°	1330°	1400°	1450°	1550°
Solubility	0.025	0.070	0.150	0.210	0.790

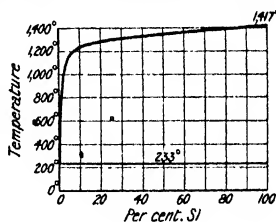

FIG. 14.—Equilibrium Diagram of Alloys of Tin and Silicon.

The solubility thus increases rapidly with rise of temp. The subject was studied by W. Manchot and H. Funk, A. M. Portevin, and L. Baraduc-Muller without obtaining any lead silicide. S. Tamaru found that the cooling curves of different alloys all show two arrests, one corresponding with the f.p. of silicon (1385°), and the other with the f.p. of lead (327°). This corresponds with the separation of the soln. into two layers near the temp. of solidification. Silicon behaves similarly with tin and with thallium.

§ 12. The Silicides of the Vanadium and Chromium Families

J. J. Berzelius¹ observed no sign of the formation of *phosphorus silicide* or *silicon phosphide* when phosphorus vapour is passed over red-hot silicon. O. P. Watts failed to prepare phosphorus silicide by reducing a mixture of phosphoric acid and silica with carbon in the electric furnace; also by using copper or copper silicide as a flux; and also by the action of phosphor tin on silicon. C. Winkler found that silicon does not unite directly with arsenic either by heating silicon with arsenic, or arsenic vap.; nor is arsenic silicide or silicon arsenide formed when silicon is heated with arsine. The silicide was not formed by melting quartz, arsenic, aluminium, and cryolite. **Arsenic pentasilicide**, or *silicon pentilarsenide*, AsSi_5 , is, however, said to be formed, mixed with arsenic dihydride when zinc silicoarsenide is treated with hydrochloric acid. It was freed from arsenic hydride by heating in a current of hydrogen; from zinc (and iron) by boiling with nitric acid; and from silica by a soln. of potassium hydroxide. The dark grey powder consists of microscopic needles; it can be heated in air without losing arsenic; acids alone, or aqua regia, are without action; boiling potash-lye attacks it very slowly, but molten alkali hydroxides or carbonates rapidly form alkali silicate and arsenate. Complex **silicoarsenides** were made by heating the metals with arsenic and silicon under cryolite and sodium chloride as fluxes. Thus, C. Winkler made **zinc silicoarsenide** in this way. The product gave off arsine when treated with hydrochloric acid and, as indicated above, left a residue of arsenic hydride and silicide. E. Vigouroux could get no *antimony silicide*, or *silicon antimonide*, by the action of antimony on silicon in the electric furnace. R. S. Williams found that molten antimony and silicon are completely miscible, and on cooling they form two series of mixed crystals extending respectively from 0.03 and from 99-100 per cent. of silicon, Fig. 15; there is no evidence of chemical combination. L. Kahlenberg observed that no silicide is formed when antimonious oxide is reduced by silicon. E. Vigouroux found that molten bismuth

dissolves silicon but rejects it again in a crystalline state on cooling; no *bismuth silicide* is formed. R. S. Williams found bismuth is insoluble in fused silicon, but silicon is soluble to the extent of about 2 per cent. in fused bismuth at 1414° ,

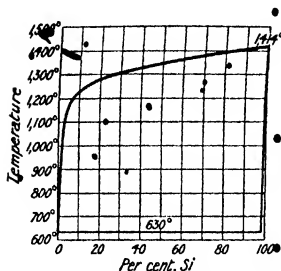

FIG. 15.—Equilibrium Diagram of Alloys of Antimony and Silicon.

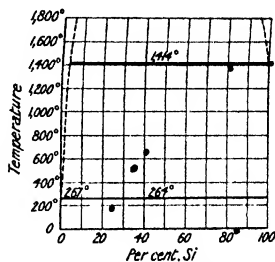

FIG. 16.—Equilibrium Diagram of Alloys of Bismuth and Silicon.

Fig. 16. The two elements form a series of mixed crystals with 0.08 per cent. of silicon. L. Kahlenberg and W. J. Trautmann observed no silicide is formed when bismuth oxide is reduced by silicon.

According to J. S. W. Johnston,² if vanadium pentoxide in a carbon crucible be heated with silicon to a high temp., a reddish-grey, metallic mass resembling bismuth is obtained. It conducted electricity very well. H. E. Roscoe suggested that the product was vanadium silicide. H. Moissan and A. Holt prepared **vanadium disilicide**, VSi_2 , by heating an intimate mixture of vanadium trioxide with a little more than five times its weight of silicon for about 2 mins. in an electric arc furnace, and treating the residue successively with potassium hydroxide soln. and conc. nitric or sulphuric acid. It can also be obtained by reducing a mixture of silicon and vanadium trioxide with magnesium; and J. Meyer and R. Backa obtained it by heating a mixture of vanadium pentoxide, silicon, and fluorspar. According to H. Moissan and A. Holt, it forms brilliant prismatic crystals which have a metallic lustre and a sp. gr. of 4.42, scratch glass, and melt and volatilize in the electric furnace. Alkalies and acids, with the exception of hydrofluoric acid, have no action on it, but it burns in fluorine, chlorine, or bromine when heated. Iodine vapour, oxygen, sulphur, and hydrogen sulphide attack it very slowly at the m.p. of glass, but hydrogen chloride converts it into silicochloroform and vanadium chloride. Fused alkali hydroxides decompose the silicide; the action of fused metals depends on whether they combine more readily with silicon or with vanadium. Copper, for example, yields copper silicide and a copper vanadium alloy. H. Giebelhausen found that mixtures of the two elements give a eutectic melting at 1411° , Fig. 17. The maximum on the curve corresponds with VSi_2 , which furnishes needle-like crystals, melting at 1655° , and harder than silicon. No solid soln. between silicon and the disilicide were observed. H. Moissan and A. Holt also made **vanadium hemisilicide**, V_2Si , (i) by heating a mixture of 120 parts of vanadium trioxide and 14 parts of silicon in the electric arc furnace; (ii) by the action of silicon on vanadium carbide, namely, by heating a mixture of vanadium trioxide, silicon, and carbon for 4 mins. in the arc furnace; and (iii) by heating a mixture of vanadium trioxide, silicon, and copper in the electric arc furnace. The hemisilicide is obtained in brilliant prismatic crystals which have a metallic lustre and a sp. gr. of 5.48 at 17° . It fuses at a temp. above the m.p. of the disilicide, and it is insoluble in water,

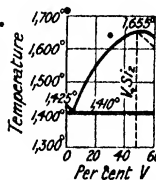

FIG. 17.—Fusion Curves of the Binary System: Si-V.

alcohol, ether, or benzene. Fluorine does not attack it in the cold; with chlorine at a red heat, it gives vanadium tetrachloride and silicon tetrachloride, and with bromine, vanadium tribromide and silicon hexabromide. It is attacked only superficially by water, sulphur, or hydrogen sulphide at a high temp., and ammonia has no action on it. It burns when heated in hydrogen chloride. When fused with an excess of silicon, it gives the disilicide. It is decomposed by molten sodium or copper, but is hardly affected by silver. Hydrochloric, nitric, and sulphuric acids do not attack it, but a mixture of nitric acid with either of the others dissolves it, and it is easily attacked by hydrofluoric acid, even in dil. soln. It is also decomposed by fused potassium hydroxide or a mixture of potassium carbonate and nitrate. O. Hönigschmid prepared **tantalum disilicide**, $TaSi_2$, by a method similar to that employed for titanium silicide. It forms iron-grey four-sided prisms having a metallic lustre resembling that of molybdenum disilicide. The sp. gr. is 8.83 at 0°. The compound is oxidized when heated in oxygen; reacts with fluorine only when heated; also reacts with chlorine when heated, but not with bromine; it dissolves in hydrofluoric acid; it is insoluble in mineral acids including aqua regia; it is soluble in a mixture of nitric and hydrofluoric acids; it is not decomposed by potassium hydrosulphate at a red heat; and it is readily decomposed by fused alkali hydroxides.

H. N. Warren³ prepared a chromium silicide by heating white hot a mixture of chromic oxide with an excess of graphitoidal silicon. It was easily attacked by hydrofluoric acid. A. Ditte and H. Moissan noted that the two elements unite directly at a high temp. P. Lebeau and J. Figueras stated that when a small quantity of silicon is melted with a mixture of chromium and copper, and the resulting button is digested with nitric acid, prismatic crystals of chromium trisilicide, Cr_3Si , remain; with a larger proportion of silicon, lozenge-shaped, faceted crystals of chromium hemisilicide, Cr_2Si , are formed; with a still larger proportion of silicon, chromium ditrisilicide, Cr_3Si_2 , is formed; and finally, with the silicon in excess, chromium disilicide, $CrSi_2$, is produced. R. Walter made the alloy directly from the elements. R. Frilley made the alloys by heating chromic oxide with silicon carbide, or a mixture of chromic oxide, silicon, and carbon; L. Baraduc-Muller used a mixture of chromic oxide, silicon carbide, and carbon. H. Moissan noted that chromium readily takes silicon from its surroundings—e.g. the materials of the crucible; and A. Burger likewise found it to occur when chromic oxide is reduced by calcium in glass or porcelain vessels.

R. Frilley found alloys with up to 10 per cent. of silicon are matte, white, compact, and hard; they have cavities lined with needle-like crystals. Alloys with 10–25 per cent. of silicon are dull and grey; they disintegrate easily, and crystallization is not well defined. Alloys with 25–70 per cent. silicon are well crystallized with cavities lined with crystals; the crystals with alloys up to 30 per cent. of silicon are acicular, those with 35–50 per cent. silicon are prismatic, probably rhombic; and with over 50 per cent. of silicon the prisms are replaced by fine needles. Alloys with over 50 per cent. silicon look like fused silicon. M. François and C. Lormand examined the structure of the crystals. The following are selected from R. Frilley's table of sp. gr., sp. vol., and mol. vol.:

Per cent. Si	0	10.24	23.21	35.00	51.00	61.91	70.10	89.12	100
Sp. gr.	6.60	6.50	5.62	5.38	4.83	3.49	3.10	2.65	2.40
Sp. vol.	0.151	0.163	0.178	0.189	0.207	0.286	0.322	0.381	0.416
Mol. vol.	7.87	7.36	7.72	7.58	7.24	9.47	10.49	11.18	11.66

He says that points of inflexion on the sp. gr. curve correspond with Cr_2Si , $CrSi_2$, and a compound *chromium silicide*, $CrSi$, which has not been isolated; there are also singularities corresponding with Cr_3Si , Cr_3Si_2 , and **chromium trihemisilicide**, Cr_2Si_3 ; the sp. vol. curve shows singularities corresponding with Cr_3Si , Cr_2Si , $CrSi$, Cr_2Si_3 , $CrSi_2$, and chromium heptahemisilicide, Cr_2Si_7 ; and the mol. vol. curve has singularities corresponding with Cr_3Si , Cr_2Si , $CrSi_2$, and Cr_2Si_7 . The trihemisilicide was isolated by L. Kahlenberg and W. J. Trautmann. R. Frilley said that all the

chromium-silicon alloys dissolve when fused with alkali hydroxides, carbonates, and nitrates, and in fused sodium dioxide. Soln. of the alkali hydroxides, cold or hot, are without action; likewise also nitric and sulphuric acids. Hydrochloric acid in the cold rapidly attacks alloys with 20-50 per cent. silicon, and is without action on the other alloys; hydrofluoric acid behaves similarly but acts more vigorously; aqua regia acts irregularly on alloys with up to 50 per cent. silicon, and is without action on the others; while a mixture of nitric and hydrofluoric acids easily dissolves these alloys. P. Lebeau and J. Figueras add that the chromium silicides are not analogous to those of manganese, iron, cobalt, and nickel.

G. J. L. de Chalmot prepared **chromium disilicide**, CrSi_2 , by heating in an electric arc furnace a mixture of chromic oxide, charcoal, and an excess of silica; and P. Lebeau and J. Figueras, by melting copper, chromium, and an excess of silicon. G. J. L. de Chalmot stated that the grey needle-like crystals have a metallic lustre; and sp. gr. 4.393. The compound is not attacked by cold hydrochloric acid or aqua regia; it is soluble in hydrofluoric acid, and in consequence the admixed free silicon can be determined. P. Lebeau and J. Figueras prepared **chromium ditritasilicide**, Cr_3Si_2 , by heating in an electric arc furnace for $\frac{1}{2}$ mins. a mixture of 100 grms. of 12 per cent. cuprosilicon, and 4 grms. of chromium, and washing the product alternately with 50 per cent. nitric acid, and dil. sodium hydroxide. L. Baraduc-Muller made it by heating a mixture of chromic oxide, silicon carbide, and carbon. E. Vigouroux passed silicon tetrachloride over pulverized chromium at 1200° , and obtained this silicide as a crystalline grey powder. P. Lebeau and J. Figueras said that this silicide crystallizes in long, quadratic prisms, has a sp. gr. 5.6 at 0° , abrades glass, but not quartz, and is stable in moist or dry air at the ordinary temp., but oxidizes superficially at 1100° . The silicide becomes incandescent when placed in chlorine at 400° , forming silicon and chromic chlorides; it reacts slowly with bromine at a red heat, but is not acted on by iodine. It is insoluble in dil. hydrochloric acid, but chromous chloride is formed by soln. of the silicide in the warm conc. acid or by the action of gaseous hydrogen chloride. It is attacked by hydrofluoric but not by sulphuric or nitric acid. Fused potassium chlorate or nitrate does not attack the silicide, but it is converted by fused alkali carbonates into the silicate and chromium sesquioxide, and by fused mixtures of alkali carbonates and nitrates into the silicate and chromate.

H. Moissan obtained **chromium hemisilicide**, Cr_2Si , by heating a mixture of silicon and carbon to 1200° in a stream of hydrogen or in a carbon crucible in the electric arc furnace; and also by heating in the arc furnace a mixture of 60 parts of silica, 200 of chromic oxide, and 70 of sugar-charcoal. In each case the product was washed with cold hydrofluoric acid; some silicon carbide was always present as impurity. P. Lebeau and J. Figueras made it by melting together a mixture of 78.22 parts of copper, 12.04 of chromium, and 8.92 of silicon, and treating the product alternately with nitric acid and a dil. soln. of sodium hydroxide. According to H. Moissan, the small prismatic crystals readily scratch quartz and corundum; at a red heat, the compound readily burns in chlorine gas; hydrogen chloride transforms it into silicon and chromium chlorides; nitric acid has no action; aqua regia decomposes the silicide; molten potassium carbonate attacks it slowly, molten potassium nitrate quickly, forming in each case silicate and chromate. According to C. Zettel, when a mixture of 140 parts copper and 140 parts of aluminium is melted in a fire-clay crucible and 200 parts of chromic oxide, previously strongly heated, is added gradually, and after strongly heating for some time a small quantity of aluminium filings, there is a very energetic action. The metallic ingot obtained on cooling contains crystals of a **chromium tritasilicide**, SiCr_3 , which is separated from the metal by the action of aqua regia. C. Matignon and R. Trannoy heated a mixture of chromic oxide, silica, and aluminium, and found the silicide separated easily from the alumina slag. L. Baraduc-Muller also made this silicide; and P. Lebeau and J. Figueras made the same compound by melting together 84.32-85.63 parts of copper, 10.83-12.83 of chromium, and 1.24-4.36

of silicon, and treating the product alternately with nitric acid and a dil. soln. of sodium hydroxide. Grey prismatic crystals remain. According to C. Zettel, the sp. gr. of the crystals is 6.52 at 18°; they scratch glass; they are decomposed by cold aq. hydrofluoric acid, but are not affected by other acids; they are readily attacked by chlorine and bromine at a red heat, by molten potassium chlorate, and by a molten mixture of potassium carbonate and nitrate; but fused potassium hydroxide attacks the silicide slowly.

H. N. Warren⁴ prepared molybdenum silicide by heating a mixture of the oxide and silicon in an oxy-hydrogen blowpipe furnace. The crystalline mass so obtained was very hard; it is decomposed by hydrofluoric acid, and by chlorine at a red heat; but other acids act on this silicide very slowly. R. Walter made the alloy directly from the elements. H. Moissan obtained a crystalline silicide by heating the constituent elements in the electric arc furnace; and L. Baraduc-Muller, by heating at 1720° for 10 mins., a mixture of 2 mols of molybdic oxide, one mol of silicon carbide, and 3 gram-atoms of carbon, using a mixture of lime and magnesia as a flux. According to E. Vigouroux, **molybdenum trihemisilicide**, Mo_3Si_3 , is obtained by heating, in a carbon crucible in the electric furnace, a mixture of crystallized silicon and the molybdenum oxides obtained by calcining ammonium molybdate; the crystalline product is disintegrated by electrolysis in hydrochloric acid, and the mixture of crystalline silicides is treated successively with aqua regia, caustic potash, and hydrofluoric acid; the removal of carbon silicide is effected by means of cadmium tungstate soln., and the residue consists of molybdenum silicide mixed with more or less iron silicide. When heated in chlorine at 300°, molybdenum silicide becomes ignited, silicon tetrachloride and molybdenum perchloride being produced. O. P. Watts prepared **molybdenum disilicide**, MoSi_2 , by fusing in an electric furnace a mixture of 70 parts of molybdic oxide, 30 of silica, 50 of boric oxide, 106 of copper, and 120 of aluminium, using cryolite as a flux, and lime to slow down the reaction; he also made it from molybdenite, silica, and calcium carbide. In either case the product was successively treated with nitric acid, and dil. hydrofluoric acid. The resulting dark-coloured crystals contained a little boron and iron. O. Hönigschmid used a mixture of 10 parts of molybdic oxide, 90 of quartz sand, 100 of aluminium filings, and 125 of flowers of sulphur. E. Defacqz fused a mixture of 90 parts of 50 per cent. cuprosilicon free from iron, and 10 parts of molybdenum for about 1½ mins. in an electric arc furnace; the product was successively treated with nitric acid, dil. sodium hydroxide, hydrochloric acid, and hydrofluoric acid (on a water-bath), and water. The non-magnetic, grey, microcrystalline plates had a sp. gr. 6.2 at 0°; O. Hönigschmid gave 5.88 at 0°; and O. P. Watts, 6.31 at 20.5°. E. Defacqz said that the silicide is not altered by heating in a blowpipe flame and, according to O. Hönigschmid, it is not affected by heating to redness in oxygen. E. Defacqz said that it is not attacked by hydrofluoric, hydrochloric, nitric, and sulphuric acids, by aqua regia, or by fused hydro-sulphates. O. Hönigschmid found a mixture of hydrofluoric and nitric acids attacks the silicide vigorously; and fluorine also acts vigorously at ordinary temp.; E. Defacqz said that it is acted on by chlorine at 350°–400°, giving silicon chloride and molybdenum pentachloride; O. Hönigschmid said that bromine has scarcely any action at a red heat. E. Defacqz found that the silicide is attacked by aqua regia containing hydrofluoric acid at the temp. of the water-bath, giving molybdic acid; and by fused alkali hydroxides or carbonates, or a mixture of these with alkali nitrates or chlorates.

H. N. Warren⁵ prepared tungsten silicide by the same process as that employed for molybdenum silicide. The product is harder than molybdenum silicide, and its behaviour towards acids and chlorine is similar. H. Moissan also found that silicon unites directly with tungsten in the electric arc furnace. R. Walter made alloys directly from the elements. The British Thomson-Houston Co. made the alloys by heating mixtures of tungstic and silicic acids and magnesium. R. Frilley said that the general methods of preparing tungsten silicides include (i) The

reduction of tungstic oxide by a mixture of silicon and carbon; (ii) Reduction of tungstic oxide by silicon carbide; (iii) Reduction of a mixture of silica by carbon and tungsten; (iv) Fusion of a mixture of tungsten and 92 per cent. ferrosilicon; and (v) The reduction of tungstic oxide in the electric furnace by an aluminium alloy with 94 per cent. silicon. He said that alloys with 5-10 per cent. of silicon are matte, yellow, and fuse with difficulty. Alloys with 10-20 per cent. of silicon are steel-grey, and are hard enough to scratch glass and agate. Alloys with 20-40 per cent. silicon are more fusible, and easily split into thin plates. Alloys with 40-60 per cent. silicon are granular and have a bluish tinge. Alloys with 60 per cent. silicon look like fused silicon. The sp. gr., sp. vol., and mol. vol. are selected from R. Frilley's table:

Per cent. Si	0	10.10	20.50	31.88	38.38	61.00	100.00
Sp. gr.	18.7	13.35	10.98	8.70	7.07	3.99	2.40
Sp. vol.	0.054	0.075	0.091	0.115	0.141	0.251	0.416
Mol. vol.	9.84	8.82	8.23	7.77	8.30	10.5	14.6

The singularities in the sp. gr. curve are taken to show the existence of the two silicides, W_2Si_3 and WSi_3 . The singularities in the sp. vol. curve correspond with the same silicides; and those in the mol. vol. curve with the hemi- and trisilicides but not with W_2Si_3 . The alloys are attacked only superficially by hydrofluoric acid, but they readily dissolve in a mixture of hydrofluoric and nitric acids. Hydrochloric, nitric, and sulphuric acids are without action. Aqua regia attacks imperfectly alloys with less than 18 per cent. silicon, and has no action on alloys with more silicon. Alloys with 18-35 per cent. of silicon are attacked only with difficulty by fused mixtures of alkali carbonates and nitrates, but alloys with more silicon readily dissolve in fused alkali carbonates. Alloys with up to 18 per cent. silicon oxidize superficially on exposure to air, but alloys with more silicon are not attacked at 1200° . Chlorine attacks the alloys at a red heat; bromine and iodine have no action at 300° .

E. Vigouroux prepared tungsten trihemisilicide, W_2Si_3 , by heating in the electric furnace a mixture of 100 grms. of silicon with 230 grms. of tungsten oxide obtained by heating ammonium tungstate. The heavy, brittle, crystalline product is suspended in dil. hydrochloric acid (1 in 10), and connected with the positive pole of a battery of two or three cells, a carbon plate placed in the liquid being connected with the negative pole. The metal dissolves, and the silicide, which collects at the bottom of the vessel, is treated successively with aqua regia, ammonia, and hydrofluoric acid, and any carbon silicide that may be present is separated by means of methylene iodide. This silicide forms steel-grey plates with a metallic lustre; the sp. gr. is 10.9. It is attacked by chlorine, with incandescence between 200° and 300° ; by bromine, without incandescence, below a red heat, and by iodine, without incandescence, above a red heat. In oxygen, it burns very brilliantly at about 500° , and in air it oxidizes below a red heat, but does not burn; nitrogen is without action at any temp. The ordinary acids, including hydrofluoric, have no action even on heating. Aqua regia is practically without action, but a mixture of nitric and hydrofluoric acids attacks the silicide violently, even at ordinary temp. Alkalies in soln. have little action, but fused alkali hydroxides and carbonates decompose the silicide very readily, whilst fused potassium nitrate acts with somewhat less energy. E. Defacqz prepared tungsten disilicide, WSi_2 , by heating copper silicide with amorphous tungsten in an electric arc furnace and washing the resulting product successively with nitric acid, sodium hydroxide soln., warm hydrofluoric acid, and water. The crystals having a lower sp. gr. than 3.4 (principally carbon silicide) were eliminated by washing with methylene iodide. The same product may also be obtained by reducing a mixture of silica and tungstic anhydride with sulphur and aluminium, the crystals being isolated from the button produced by the method already described, nitric acid being replaced by hydrochloric. O. Hönigschmid employed a similar process. This silicide is dimorphous, for when prepared by the second method it occurs in brilliant, bright, grey, prismatic

needles, but when obtained from copper silicide it forms masses of brilliant, grey crystals. The sp. gr. is 9.4 at 0°. O. Hönigschmid gave 9.3 at 0°. The compound is not magnetic, and remains unaltered at 900° in air, is decomposed by copper at 1200°, forming copper silicide and tungsten, and is not affected by sulphuric acid or aqua regia, but is attacked by a mixture of hydrofluoric and nitric acids, yielding tungstic anhydride as a residue. Fused alkali hydroxides or carbonates convert it into the alkali silicate and tungstate, but melted potassium hydrogen sulphate is without action. Dry chlorine attacks the silicide easily at about 450°, yielding a mixture of silicon tetrachloride and tungsten hexachloride, and this reaction can be utilized for the analysis of the compound. According to R. Frilley, tungsten trisilicide, WSi_3 , is obtained by reducing silica by carbon in the presence of molten tungsten. The resulting alloy is powdered to pass a 100's sieve, washed with conc. hydrofluoric acid to remove ferrosilicon, with a hot conc. soln. of sodium hydroxide to dissolve graphitoidal silicon, and with dil. hydrofluoric acid to remove silica. The small white crystals are attacked by chlorine at a red heat; they are not attacked by hydrofluoric, hydrochloric, nitric, or sulphuric acid; but a mixture of nitric and hydrofluoric acids attacks it vigorously. Molten sodium hydroxide attacks it slowly. A. Pacz described the use of alloys of tungsten with 1-3 per cent. of silicon as filaments for incandescent electric lamps.

E. Defacqz prepared uranium disilicide, USi_2 , from a mixture of 250 parts aluminium, 250 of sulphur, 180 of silica, and 56 of uranium oxide. The mixture after ignition and cooling was treated successively with hot 10 per cent. hydrochloric acid, and dil. sodium hydroxide; then with conc. hydrochloric acid, and hot nitric acid to eliminate any uranium-aluminium alloy; and finally, with dil. sodium hydroxide, dil. hydrochloric acid, and water. The pale grey microscopic crystals belong to the cubic system; and they have a sp. gr. of 8 at 0°. Chlorine attacks this silicide at 500°, giving the chlorides of uranium and silicon. Cold hydrogen fluoride dissolves it readily, whilst oxidizing agents have little action. Although stable in air at a red heat, it burns slowly in oxygen at 800°, and is decomposed on fusion with alkalis, alkali carbonates, or potassium hydrosulphate.

§ 13. The Silicides of Manganese and of the Iron Family

Manganese silicide was made by C. Brunner¹ by reducing manganese oxide with carbon in the presence of silica; the regulus contained 6-8 per cent. of silicon. The manganese prepared by C. Brunner by reducing the halide with sodium always contained over one per cent. of silicon, and if the reduction occurred in the presence of silica or potassium fluosilicate, the product contained nearly 10 per cent. silicon. F. Wöhler made a silicide by heating manganous fluoride, cryolite, water-glass, and sodium covered with a mixture of sodium and potassium chlorides in a fireclay crucible; by melting a mixture of sodium fluomanganite, fluor spar, water-glass, and sodium; or a mixture of manganous chloride, fluor spar, potassium fluosilicate, and sodium; or a mixture of manganous chloride, quartz sand, cryolite, and sodium. H. N. Warren heated manganese oxide and silicon to a white heat; C. Matignon and R. Trannoy used the thermite process with a mixture of manganese oxide, silica, and aluminium; and L. Troost and P. Hautefeuille found the elements unite directly at a high temp. R. Walter used a similar process. E. F. Price smelted electrically a mixture of manganese, silicon, and carbon. According to P. Lebeau, commercial manganese obtained by the thermite process contains manganese silicide, and commercial manganese silicide is a mixture of Mn_2Si and $MnSi$ with a little iron and silicon carbide, and a trace of calcium. M. A. Sanfourche studied the limiting range of silicon in these alloys.

According to R. Frilley, alloys with 2-10 per cent. of silicon are lustrous and grey, those with 8 per cent. have the appearance of a mass of steel-grey, prismatic crystals. Alloys with 10-30 per cent. of silicon are whiter and more lustrous, and the crystals increase in the alloys with up to 25 per cent. of silicon and form large confused masses. Alloys with 30-45 per cent. of silicon are grey and matte, and spontaneously break up into powder. Alloys with 45-50 per cent. of silicon are very lustrous, and resemble ferrosilicon with 50 per cent. Si. Alloys with over 50 per cent. silicon appear like masses of crystalline silicon. The sp. gr., sp. vol., and mol. vol. of a selection from R. Frilley's table are:

Per cent. Si	0	8.8	20.18	33.60	45.28	59.68	82.70	100.00
Sp. gr.	7.40	6.17	5.80	5.35	4.95	3.62	2.74	2.40
Sp. vol.	0.135	0.162	0.172	0.181	0.215	0.276	0.365	0.415
Mol. vol.	7.43	8.21	7.92	7.53	8.21	9.63	11.17	11.66

The sp. gr. curve shows singularities corresponding with Mn_2Si , $MnSi_2$, $MnSi$, and manganese pentasilicide, Mn_5Si . The sp. vol. curve shows singularities corresponding with $MnSi$, $MnSi_2$, but not Mn_2Si ; and with the mol. vol. curve there are singularities with Mn_5Si , $MnSi$, and $MnSi_2$, but not Mn_2Si . The alloys are all brittle, and fracture easily. L. Baraduc-Muller studied their coeff. of expansion; and F. Dörinckel, their m.p. The f.p. curve, Fig. 18, shows two maxima at 21.3 and 33.8 per cent. by weight of silicon respectively, corresponding with the composition of the compounds Mn_2Si and $MnSi$, as well as three eutectic points at 1075° and 11 per cent., at 1239° and 30 per cent., and at 1135° with 50 per cent. by weight of silicon respectively. Between 50 and 100 per cent. by weight of silicon, microscopic observations indicate the presence of a third compound, the crystals of which are characterized by fine parallel markings, but its composition

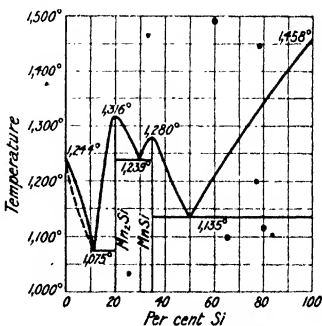

FIG. 18.—Equilibrium Diagram of Manganese-Silicon Alloys.

could not be determined by thermal analysis owing to the slight alteration in the m.p. of the alloy with change of conc. from 45–50 per cent. silicon. The compound in question cannot be MnSi_2 , which would contain 50.8 per cent. of silicon, whereas crystals of the latter element can be detected in alloys containing only 50 per cent. of silicon. P. Lebeau by treating the alloys with various solvents and analyzing the residues, has arrived at the conclusion that three compounds of manganese and silicon exist, the respective formulæ of which are Mn_2Si , MnSi , and MnSi_2 . From alloys containing 0–10 per cent. of silicon, mixed crystals separate. L. Troost and P. Hautefeuille studied the heats of formation of the manganese silicides. E. Wedekind showed that unlike many other manganese compounds, the silicides are always non-magnetic. G. Tamman measured the electrode potentials.

R. Frilley found that alloys low in silicon are oxidized in moist air at a red heat, being covered by *une pellicule irisée*; those with over 30 per cent. silicon are not oxidized at 1000°. Chlorine, bromine, and iodine readily attack the alloys at a red heat. Hydrochloric acid easily dissolves in the cold, alloys with up to 20 per cent. silicon; with more siliceferous alloys the attack becomes feebler, and is superficial and scarcely perceptible with alloys having over 45 per cent. silicon. Hydrofluoric acid alone dissolves in the cold all alloys with up to 50 per cent. silicon; the residue contains a little carbon present as impurity; the attack with alloys having over 50 per cent. silicon is only partial, and a residue of graphitoidal silicon remains. A mixture of nitric and hydrofluoric acids readily dissolves these alloys. Conc. or dil., hot or cold sulphuric acid is without action; nitric acid partially attacks alloys with less than 20 per cent. silicon, and is without action on more siliceferous alloys. Manganese-silicon alloys are readily attacked by fused alkali hydroxides or carbonates, or better a mixture of alkali carbonate and nitrate. Dil. aq. soln. of alkali hydroxides slowly attack all alloys with over 20 per cent. of silicon, and with a prolonged action, the residue has nearly 20 per cent. silicon. W. Jenge studied the action of soln. of chlorides, bromides, iodides, nitrates, sulphates, sodium hydroxide, sulphuric acid, and hydrochloric acid on manganese silicides. He found that only MnSi_2 was non-resistant to acids, and all the silicides were resistant to sodium hydroxide.

P. Lebeau made **manganese hemisilicide**, Mn_2Si , by heating in a covered carbon crucible in an electric furnace, a mixture of 10 grms. of crystalline silicon, and 100 grms. of cupromanganese with 22.35 per cent. Mn. The regulus was treated alternately with 50 per cent. nitric acid, and a 10 per cent. aq. soln. of sodium hydroxide; he also heated to redness a mixture of sodium (184 parts), potassium fluosilicate (264 parts), manganese oxide (92 parts Mn_2O_3), and copper (100 parts). E. Vigouroux prepared the same silicide (i) by heating silicon with nine times its weight of manganese in the electric furnace and treating the product first with water, then with dil. hydrochloric acid, and finally, and rapidly, with dil. hydrofluoric acid; or (ii) by heating in the electric furnace a mixture of 1 part of silica, 3 parts of manganoso-manganic oxide, and one part of sugar-carbon, and treating the product as above; or better, (iii) by heating silicon with 4 or 5 times its weight of manganoso-manganic oxide in a porcelain dish in an atm. of dry hydrogen up to the softening point of porcelain; (iv) by firing a mixture of silica, manganese oxide, and aluminium, and allowing the flux to cool very slowly, a brittle mass is obtained which, after extraction with dil. hydrochloric acid and then with dil. hydrofluoric acid, consists of crystals of the manganese hemisilicide, Mn_2Si , which is decomposed by the action of warm hydrochloric or nitric acid, and in this respect differs from P. Lebeau's compound of the same composition? Attempts to prepare a silicide containing a higher proportion of manganese than the one described above were not successful. Manganese hemisilicide, said E. Vigouroux, furnishes well-defined crystals lustrous and steel-grey; it is hard and brittle; its sp. gr. = 6.6 at 15°. P. Lebeau gave 6.20 at 15°. According to E. Vigouroux, it does not alter when exposed to air, and melts at the temp. of the reverberatory furnace. Fluorine attacks it at the ordinary temp., chlorine at about 500°, and iodine and bromine

at higher temp.; oxygen and air attack it at a red heat. Dry hydrogen fluoride decomposes it readily, especially if gently heated, hydrogen chloride below a red heat, and hydrogen iodide at higher temp.; water is without action at 100°, but at a red heat decomposes the silicide with liberation of hydrogen. Dil. acids attack it readily, and conc. acids, especially hydrofluoric acid, are violent in their action; an aq. soln. of potassium hydroxide is without effect, but the solid substance attacks the finely powdered silicide when heated with it, and fused alkali carbonates or mixtures of carbonate and nitrate oxidize it readily. M. Wunder and B. Jeanneret found that hot phosphoric acid of sp. gr. 1.75 dissolves manganese silicide, forming a clear liquid.

A. Carnôt and E. Goutal found that when commercial manganese is dissolved in dil. sulphuric acid with the exclusion of air, an amorphous powder, probably **manganese silicide**, MnSi , remains. P. Lebeau prepared this compound by the process employed for the hemisilicide using 25 grms. of silicon to 100 grms. of the cupromanganese in the one process, and 100 grms. of sodium, 215 grms. of potassium fluosilicate, 23 grms. of manganese oxide, and 50 grms. of copper in the other. This silicide furnishes lustrous tetrahedral crystals of sp. gr. 5.90 at 15°; they scratch topaz, but not corundum. Steam, and oxygen at 1000°, oxidize the silicide only superficially; it is readily attacked by the halogens; the hydrogen halides attack it easily; boiling hydrochloric acid attacks it superficially; hydrogen sulphide has no action at 800°; nitric acid and sulphuric acid, hot or cold, dil. or conc., do not attack the silicide; carbon at a high temp. forms silicon carbide and manganese; and silicon forms the higher silicide. G. J. L. de Chalmot prepared an impure **manganese disilicide**, MnSi_2 , by melting together manganese oxide (5 parts), wood charcoal (15 parts), quartz (40 parts), and calcium oxide (15 parts) in an electric furnace. P. Lebeau employed the same process in the case of the hemisilicide, but using 14.9 per cent. of copper, 80.43 of silicon, and 3.25 of manganese. The disilicide forms small, dark grey, apparently octahedral crystals having a density 5.24 at 13°; it is not attacked by nitric or sulphuric acid, but is readily soluble in hydrofluoric acid and quickly decomposed by conc. aq. soln. of alkali-hydroxides.

According to G. Gin, when rhodonite is reduced in the electric furnace a crystalline alloy of silicon and manganese is obtained and its analysis indicates that it contains 95 per cent. of crystalline **manganese ditrisilicide**, Mn_3Si_2 , which forms brilliant, prismatic crystals, sometimes 5 cms. long; the sp. gr. is 6.05 at 15°, and the m.p. 1250°–1300°. The compound is attacked by chlorine with incandescence at a red heat; it is not changed by oxygen at the ordinary temp., but is superficially oxidized at 500°; and it is readily attacked by the gaseous halogen acids, by nitric or hydrochloric acid or aqua regia, or by fused alkali carbonates or mixtures of carbonates and nitrates, whilst sulphuric acid has no action on the compound. P. Lebeau questions the existence of this silicide as a chemical individual.

Near the beginning of the last century, H. Davy² found that an iron wire heated electrically to whiteness in contact with silica slightly moistened, and in hydrogen gas, becomes brittle and whiter, and furnishes silica when dissolved in acids. H. Davy here obtained a soln. of silicon in iron. J. J. Berzelius also obtained an analogous product by heating silica and carbon in the presence of iron. He later heated to whiteness a mixture of potassium fluosilicate and iron filings, and washed the iron and potassium fluorides with hot water. The resulting iron silicide dissolves in acids—even in hydrofluosilicic acid. E. D. Clarke exposed silica in contact with iron in a charcoal crucible to the oxy-hydrogen blowpipe flame and also obtained a soln. of silicon in iron, or of iron in silicon. O. Hackl found ferrosilicon in commercial calcium carbide. J. B. J. D. Boussingault fused iron in a fireclay crucible and obtained an alloy with 0.54 per cent. of silicon—presumably derived from siliceous materials of the crucible. He said that the alloy was more difficult to file and to hammer than iron without the silicon. H. St. C. Deville and H. Caron prepared alloys of iron and silicon, and said that a kind of silicon-steel—*fonte siliciée*—is produced which has many properties in common

with the ordinary carbon-steel. C. Winkler confirmed this result without isolating any definite compound. H. Moissan found that if a cylinder of soft iron be embedded in crystals of silicon, and heated at the temp. of a good forge, the silicon penetrates to the centre of the cylinders although the iron does not fuse, and a silicide is formed. This is taken to show that silicon has a distinct vap. press. below its m.p. P. Lebeau found that the combination occurs even at 950° , and says the process resembles the cementation of iron by carbon. L. Grenet, P. Lebeau, J. E. Stead, H. Moissan, and R. T. Haslam and L. E. Carlsmith studied the cementation of silicon in steel; and H. G. C. Fairweather, the alloys of silicon, chromium, and manganese.

Iron-silicon alloys are made commercially and used as a means of introducing specified proportions of silicon into steel, but mainly as a deoxidizer. The alloys were formerly made in a blast furnace, and contained about 14 per cent. of silicon—the maximum was about 20 per cent. To-day, the alloys are made in electric furnaces, with a content 25–30, 45–55, and 75–80 per cent. silicon, and even with 90 per cent. silicon. E. Donath and M. Haissig recommend the term **ferrosilicon** be used for iron-silicon alloys with more than 5 per cent. silicon; W. Pick and W. Conrad have discussed this subject. A. Ledebur says that the term *Siliziumeisen* should be used for iron alloyed with small proportions of silicon, and *Ferrosilizium* for iron alloyed with high proportions of silicon. The name *ferrosilicine* was suggested by C. U. Shepard for a meteoritic iron–iron, 84.00 per cent., silicon, 13.57 per cent.—found at Rutherford (North Carolina). J. W. Mallet suggested that iron silicide was contained in the iron from Staunton (Virginia), and C. Winkler likewise found iron silicide—possibly Fe_2Si —in the iron from Rittersgrün (Saxony).

According to R. Walter, the reaction between iron and silicon begins at about 1250° , and owing to the rapid development of heat, the temp. rises to about 1800° . Ferrosilicon is made commercially in several grades determined by the proportion of silicon. The analyses in Table I are selected from the report of S. M. Copeman,

TABLE I.—ANALYSES OF COMMERCIAL FERROSILICONS.

	Electric furnace.					Blast furnace.
	30 per cent.	50 per cent.	75 per cent.	90 per cent.	95 per cent.

S. R. Bennett, and H. W. Hake. The blast furnace product had 0.06 per cent. arsenic, and the iron was determined by difference. In general, the charge consists of a mixture of steel turnings, anthracite coal, and quartz. The proportion of iron is determined by the desired percentage of silicon in the ultimate product. The mixture is shovelled into the electric resistance furnace, and replenished as often as room is afforded by the melting of that already in the furnace. The molten alloy is removed from the bottom of the furnace by periodical tapping—say every 45 mins.—and run into a bed of sand, and the surface of the molten ingot is skimmed with a piece of green-wood to remove the slag. When the alloy has cooled, it is broken into pieces, and packed for transport. The furnace is circular and built of firebrick, with one vertical graphite cathode suspended over the mouth of the

furnace, and the anode forms a portion of the floor. The anode is made by ramming prepared retort carbon or graphite into an opening in the floor of the furnace. Arrangements are made for raising or lowering the vertical electrode as desired. The temp. of the furnace approximates 2000° . The process is continuous, and the furnaces may be run for over a year without stopping. The electrodes are sometimes water-cooled and they are renewed every few days. In one furnace, a ton of 30 per cent. ferrosilicon required 3500 kilowatt hours; and in another 200 h.p. were needed per ton of 30 per cent. ferrosilicon. The impurities in the final product are determined by the impurities present in the raw materials. There are many modifications in detail.

A large number of patents has been registered—by J. Holloway, E. A. O. Viel, H. Aschermann, B. Scheid, G. Gin, L. d'E. Muller and L. H. Baraduc-Muller, C. A. Keller, E. Straub, M. F. Matt, H. N. Potter, E. F. Price, F. J. Tone, F. Laur, K. A. Kühne, E. Jüngst and R. Mewes, A. Sinding-Larsen, M. von Schwarz, V. C. Bertholus, C. H. Homan, F. J. Tone, W. Conrad, W. Pick, R. Amberg, etc.—for the preparation of ferrosilicon. G. J. de Chalmot used a mixture of iron ore, sand, and coke; H. Aschermann used a mixture of iron sulphide and quartz: $\text{FeS} + \text{SiO}_2 = \text{SO}_2 + \text{FeSi}$; W. Rathenau used a mixture of lime, anthracite, silica, and iron, and obtained both calcium carbide and ferrosilicon. W. Borchers and A. Dorsemagen heated ferruginous zinc blende, quartz, iron, and coke in a closed electric furnace and collected the zinc simultaneously given off. G. Gin used barium sulphate, ferric oxide, quartz, and carbon; and represented the reactions $\text{BaSO}_4 + \text{SiO}_2 + \text{C} = \text{BaSiO}_3 + \text{SO}_2 + \text{CO}$; and $\text{BaSiO}_3 + \text{Fe}_2\text{O}_3 + 5\text{C} = \text{Fe}_2\text{Si} + \text{BaO} + 5\text{CO}$. E. A. O. Viel and M. Jeantet fused a mixture of clay with iron in an electric furnace.

Silicides with $\text{Fe}:\text{Si} = 3:1, 2:1, 5:2, 3:2, 3:4, 1:1, 1:2$, and $1:3$ have been reported. **Iron trisilicide**, Fe_3Si , has not been isolated, and it does not appear on W. Guertler and G. Tammann's diagram, Fig. 18; its existence has not been well-established. T. Naske assumed that ferrosilicon made in the blast furnace contained the trisilicide which he isolated by treatment with dil. sulphuric acid. A. Carnot and E. Goutal found that siliceferous spiegeleisen, with 20 per cent. manganese, contained *manganese iron trisilicide*, $(\text{Mn}, \text{Fe})_3\text{Si}$, which they isolated by treatment with dil. sulphuric acid. A. Jouve also found characteristic crystals of the hemisilicide in commercial ferrosilicons. E. D. Campbell and co-workers have studied the heat of soln. of silicon in molten iron and, by analogy with the well-defined iron tritacarbide, Fe_3C , compute for the heat of formation $(\text{Fe}_3\text{Si})_n = 133.1$ cal.; and for the reaction $\text{Fe}_3\text{C} + \text{Si} = \text{C} + \text{Fe}_3\text{Si} + 17.6425$ Cals. H. Hahn described the formation of **iron hemisilicide**, Fe_2Si , by melting together iron (40 grms.), silicon (5 grms.), sodium (25 grms.), ammonium chloride (150 grms.), and sodium chloride (80 grms.). According to H. Moissan, the hemisilicide is obtained (i) by heating iron to the softening point of porcelain in a porcelain dish brasqued with silicon. (ii) By heating iron with one-tenth its weight of silicon in a crucible in the electric furnace for four minutes with an arc from a current of 900 amperes at 50 volts. With a higher proportion of silicon, the product is not attacked by acids. (iii) By heating in the electric furnace a mixture of ferric oxide with excess of silicon, silica being volatilized. In all cases, the product is treated with nitric acid dil. with four times its volume of water. The iron silicide forms small, magnetic, prismatic crystals, with a metallic lustre; sp. gr. ≈ 7.00 at 22° . Its m.p. is higher than that of cast iron and lower than that of wrought iron. Hydrofluoric acid attacks it readily, and hence it is not identical with the silicide of sp. gr. 6.11 at 23° . H. Hahn said that it is not attacked by this acid. Hydrochloric acid slowly attacks the finely powdered silicide; nitric acid has no action, but aqua regia decomposes it, with formation of silica. The gaseous hydrogen halides attack it at temp. varying from dull to bright redness. Potassium nitrate and chlorate, at their m.p., have no action on it; fused alkali carbonates attack it slowly, and a fused mixture of a nitrate and a carbonate decomposes it

readily. P. Lebeau prepared a hemisilicide by strongly heating iron with twice its weight of commercial copper silicide containing 10 per cent. of silicon, the product being treated with nitric acid (1 : 10) and purified in the usual way. It forms long, brilliant, grey crystals with octahedral terminations. In sp. gr. and chemical properties, it is identical with H. Moissan's silicide; and it can be isolated from commercial ferrosilicons which contain 10-20 per cent. of silicon and have been prepared at a high temp. E. Vigouroux obtained the hemisilicide by the action of silicon tetrachloride on iron at a dull red heat or at 1100° . A. Carnot and E. Goutal found that spiegeleisen poor in manganese furnishes prismatic crystals of the hemisilicide when treated with very dil. sulphuric acid, and treating the residue successively with a soln. of potassium hydroxide and dil. sulphuric acid. It differs from H. Moissan's hemisilicide in being readily attacked by hot dil. acids. T. Murakami obtained no evidence of the hemisilicide on the equilibrium diagram; and W. Gontermann regarded it as a sat. solid soln. of iron monosilicide in iron.

A. Carnot and E. Goutal found that when iron is dissolved in dil. hydrochloric acid out of contact with air, the greater part of the silicon is left undissolved in the form of an iron silicide, FeSi. The remainder of the silicon is converted into the hydroxide, $\text{SiO}(\text{OH})_2$, and seems to exist in the iron in the form of silicides intermediate between iron ditritasilicide, Fe_3Si_2 , and iron dipentasilicide, Fe_2Si_3 . When the iron contains manganese, practically the whole of the latter is found in combination with the silicon in the insoluble residue, and it would seem to follow that silicon combines with manganese in preference to combining with iron. J. T. Pelouze and E. Frémy also prepared crystals of what was regarded as iron ditritasilicide, Fe_3Si_2 , in 1864; and octahedral crystals are produced by melting together quartz, iron, and carbon; and G. J. L. de Chalmot by heating the same materials in an electric furnace, and washing the product with dil. hydrofluoric acid. The last-named said that the sp. gr. is 6.36, and that the compound readily dissolves in aqua regia, hydrofluoric acid, and in fused alkali carbonates. A. Jouve doubted the existence of these silicides; W. Guertler and G. Tammann found no signs of them on the f.p. curve, Fig. 18, but R. Frilley found evidence of Fe_3Si_2 of iron trihemisilicide, Fe_3Si_3 , and of iron tritritasilicide, Fe_3Si_2 , on the sp. gr. curve. There is no other evidence of the existence of Fe_3Si_2 and Fe_2Si_3 .

H. Hahn made crystals of an iron silicide by reducing sodium chloroferrate with sodium in the presence of sodium fluosilicate. The analysis corresponds with $\text{Fe}_{10}\text{Si}_9$, and he assumed it to be a mixture of iron hemisilicide and iron monosilicide, FeSi. The sp. gr. was 6.239 at 19° . E. Frémy made the monosilicide by the action of silicon tetrachloride on red-hot iron. The yellowish-grey octahedral crystals were very hard; insoluble in aqua regia; and were decomposed by fused alkali carbonates. E. Vigouroux could not make the monosilicide by E. Frémy's process; he obtained the hemisilicide $\text{SiCl}_4 + 4\text{Fe} = 2\text{FeCl}_2 + \text{Fe}_2\text{Si}$, at a dull red heat or at 1100° . P. Lebeau produced this silicide by heating iron with an excess of copper silicide. He said that this silicide is sometimes found in geodes in commercial ferrosilicon. A. Carnot and E. Goutal (*vide supra*), and A. Jouve also noted crystals of the monosilicide in ferrosilicon. In the interior of the siliceous mass obtained from an electric furnace in which coke, sand, and lime were heated together at a temp. of about 3000° , B. L. Vanzetti found metallic buttons having a sp. gr. 5.76-6.29, a hardness of about 7 on Mohr's scale, and the composition FeSi—*vide infra* for sp. ht. The chemical characters of the substance point to its being a chemical individual, as also does the absence of magnetic properties. The iron, which occurs to the extent of 3 per cent. as ferric oxide in the coke, doubtless combines firstly with carbon, the latter being subsequently displaced by silicon formed by reduction of the silica present. Similar experiments at a higher temp. than 3000° yielded masses varying in appearance and sp. gr. (3.96-5.54) and more readily acted on by reagents than FeSi. W. Guertler and G. Tammann observed the formation of this compound in their study of the f.p. curve of iron-silicon alloys, Fig. 19; and R. Frilley obtained evidence of its existence on the sp. gr. curve.

T. Murakami found evidence of iron tritritasilicide, Fe_3Si_2 , on the equilibrium

diagram; above 1100° , it dissociates into iron and the monosilicide; the trisilicide separates primarily at about 1020° in alloys containing over 23 per cent. of silicon, and it is formed by the union of iron with the monosilicide. H. Hahn treated the regulus of iron hemisilicide with dil. hydrofluoric acid and obtained a crystalline residue corresponding with iron disilicide, FeSi_2 ; G. J. L. de Chalmot found crystals of this compound, along with Fe_3Si_2 , in 39-50 per cent. ferrosilicon. He said that since both silicides are attacked by hydrofluoric acid, it is difficult to separate them. The mixture is suspended in water, and the acid gradually added in small quantities at a time. He said that this silicide is brittle, crystalline, and non-magnetic, and has a sp. gr. 4.851. P. Lebeau obtained small lustrous crystals of the disilicide by treating iron with an excess of silicon in an electric furnace; the results with copper silicide and iron were negative. He said that the dark grey crystals have a sp. gr. 5.40 at 15° ; their hardness is between 4 and 5. The disilicide is oxidized superficially in oxygen at 1200° ; it inflames in contact with cold fluorine, and at a dull red heat in chlorine or bromine; iodine reacts

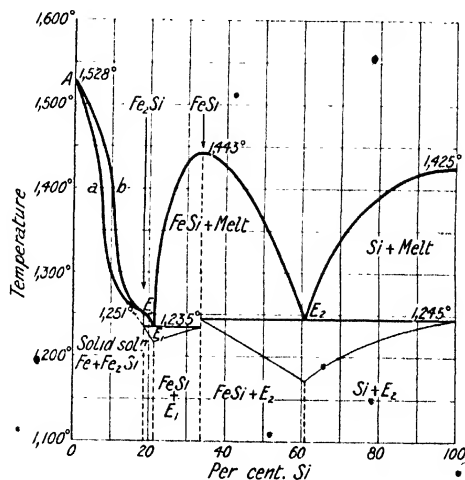

FIG. 19.—Equilibrium Diagram of Iron-Silicon Alloys.

less energetically at a still higher temp. All mineral acids, hot or cold, dil. or conc., are without action, but hydrofluoric acid reacts slowly in the cold and rapidly when heated. Soln. of alkali hydroxides have no appreciable action in the cold, but they act slowly when heated. Molten alkali hydroxides quickly decompose the disilicide. A. Jouve regards the alleged disilicide as a mixture. T. Naske claimed to have isolated iron trisilicide, FeSi_3 , by treating 50 per cent. ferrosilicon with hydrofluoric acid, but the inference has not been confirmed.

The equilibrium diagram, Fig. 19, of the silicon-iron alloys has been worked out by W. Guertler and G. Tammann, A. T. Lowzow, N. Kurnakoff and G. Urasoff, and T. Murakami. According to W. Guertler and G. Tammann, for all alloys with up to about 20 per cent. silicon, solidification begins by the formation of solid soln. of iron and the hemisilicide, Fe_2Si , in the region $AabE$; below AaE , there is a solid soln. with Fe_2Si , forming primary crystallites. Hence, 20 per cent. ferrosilicon is iron hemisilicide melting at 1251° . The microstructure depends on the rate of cooling. Alloys with 20-21.6 per cent. silicon have the f.p. curve EE_1 ; with a portion above 1235° consisting of the hemisilicide and melt, and below

1235°, of the hemisilicide and the eutectic E_1 . The remainder of the diagram explains itself. M. A. Sanfourche discussed the limiting range of silicon in these

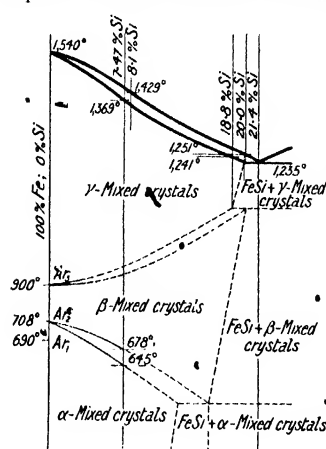

FIG. 20. --Equilibrium Diagram of Iron with up to 20 per cent. Silicon.

alloys. W. Gontermann worked out a more detailed diagram, Fig. 20, for alloys with up to 21.4 per cent. of silicon, where the dotted lines refer to curves not established by experiment. The assumption is made that with less than 15 per cent. silicon two different crystals are formed on cooling, namely, the mixed crystals of iron and silicon containing about 15 per cent. of silicon, and crystals of the composition FeSi. Silicon is soluble to the extent of about 15 per cent. in all the allotropic forms of iron. The effect of silicon on the allotropic forms of iron is also illustrated in the diagram. From the observations of F. Osmond, J. O. Arnold, P. Oberhoffer, and T. Baker, it follows that

(i) the transformation $\alpha\text{-Fe} \rightleftharpoons \beta\text{-Fe}$ is not affected by additions up to 2.7 per cent. silicon; and the transformation

$\gamma\text{-Fe} \rightleftharpoons \delta\text{-Fe}$ is lowered as in the following manner, determined by R. Ruer and R. Klesper:

Per cent. Si	0	0.2	0.4	0.6	0.8	1.0	1.2
Transition temp., °	1101°	1401°	1392°	1385°	1375°	1355°	1335°

C. Schools studied the effect of silicon on the solubility of iron carbide in γ -iron. G. J. Snelus, L. L. de Koninck and A. Ghilain, etc., tried to find how the silicon is associated with the iron. E. H. Morton and L. Troost and P. Hautefeuille, said that the silicon is chemically combined and not mechanically mixed. According to R. Frilloy, alloys with 5–15 per cent. of silicon have the appearance of grey steel. Alloys with 15–35 per cent. of silicon are compact, white, lustrous, and are readily fractured under the hammer. Alloys with 35–55 per cent. of silicon are lustrous and grey, and they are not readily fractured under the hammer. Alloys with over 55 per cent. silicon have the colour of fused silicon, and crystals of silicon are often present. Geodes lined with crystals are also present.

The **microstructure** of the alloys has been investigated by M. von Schwarz, F. Osmond, J. O. Arnold, T. Baker, L. Guillet, M. François and C. Lormand, E. Gumlich and P. Goerens, A. B. Albro, P. Paglianti, T. D. Yenson, W. Guertler and G. Tammann, etc. The general results show that with less than 15 per cent. silicon, there is only one kind of crystal present in the alloys; with the low silicon steels when carbon is present, cementite crystals are also present; when over 3 per cent. of silicon is present, carbon separates as graphite and not cementite. According to J. H. Andrew, what W. Gontermann regarded as the Ar_{1-3} break in the cooling curve of iron was in reality the Ar_{2-3} break. It is probable that with as much as 10 per cent. of silicon, this point is raised to the temp. of freezing, α -iron being formed immediately on freezing and the carbon thrown out of soln. He suggests some modifications in W. Gontermann's diagram to cover the elimination of the Ar-point. W. Gontermann, and F. Wüst and O. Petersen studied the ternary system: Iron-carbon-silicon. They found:

Per cent. Si	0.13	0.66	1.41	2.68	3.69	4.86	13.54	26.93
Per cent. C	4.29	4.05	3.88	3.56	3.32	3.08	1.94	0.87
F.p.	1138°	1152°	1160°	1185°	1197°	1210°	1233°	1255°

The solubility of carbon in iron is diminished by silicon, and carbon is precipitated if sufficient silicon be present—say 4 per cent. The carbon separates as graphite, even when the soln. is rapidly cooled from the molten state. W. Gontermann suggested that the graphite is partly formed by the dissociation of a silico-cementite, and partly as a deposit from a supersaturated soln. of silico-austenite. According to H. Moissan, the fact that the displacement of carbon by silicon is not quite complete is probably due to the establishment of a state of equilibrium between the iron silicide and the iron carbide, the conditions of equilibrium varying with the temp. and with the impurities which are always present in white or grey cast iron. G. Phragmen found that with iron containing above 17 per cent. of silicon, the **X-radiogram** of iron became weak, and at 30 per cent. silicon was entirely replaced by one corresponding with FeSi; at 40 per cent. silicon the lattice of FeSi₂ appeared; and at 50 per cent. silicon, this alone existed. No signs of Fe₃Si or of Fe₃Si₂ were observed. G. Tammann discussed the space-lattice of iron hemisilicide. G. Tammann and K. Dahl tested the brittleness of the silicide. They found no gliding planes, and noted that the alloy becomes soft 50° below the m.p.

Determinations of the **specific gravity** have been made by F. Stromeyer, who found 7.3241–6.7777 for alloys with 2.2–9.3 per cent. of silicon, H. Hahn, J. L. Smith, T. Turner, R. A. Hadfield, A. T. Lowzow, P. Paglianti, H. Moissan, G. J. L. de Chalmot, P. Lebeau, H. von Jüptner, W. Guertler and G. Tammann, B. L. Vanzetti, J. W. Rothe, L. Weiss and T. Engelhardt, H. W. Hake, M. F. Matt, O. Hengstenberg, M. von Schwarz, E. Maey, S. R. Bennett, etc., also made determinations. The following is a selection from R. Frilley's measurements of the sp. gr., sp. vol., and mol. vol.:

Per cent. Si .	5.90	11.81	20.24	40.09	50.00	77.25	92.21	100.00
Sp. gr. .	6.80	6.63	6.33	5.18	4.50	2.85	2.57	2.40
Sp. vol.	0.146	0.151	0.158	0.193	0.220	0.351	0.380	0.416
Mol. vol.	7.77	7.56	7.37	7.74	8.29	11.1	11.3	11.7

He added that the curves show five points of inflexion corresponding with Fe₂Si, Fe₃Si₂, Fe₃Si₃, Fe₂Si₂, and FeSi₂, with a singularity corresponding with FeSi. The sp. vol. curve has singularities corresponding with FeSi and FeSi₂; and the mol. vol. curve has one singularity corresponding with FeSi. C. J. B. Karsten observed that iron was hardened by the addition of 0.37 per cent. of silicon; D. Mushet observed that when iron is melted with quartz it becomes harder and more brittle. J. B. J. D. Boussingault, L. Guillet, R. A. Hadfield, W. Mrazek, T. Baker, P. Paglianti, W. A. Tilden, W. C. Roberts-Austen, and T. Turner, W. Guertler and G. Tammann, etc., made observations on the **hardness** of iron-silicon alloys. R. Janoyer said that silicon exercises a bad influence on iron, while H. Caron maintained that it has a good influence. G. A. Bisset, C. F. Burgess and J. Aston said that iron with one per cent. of silicon is soft, and it is hard and brittle with 6–7 per cent. of silicon. M. von Schwarz found for the Shore's scleroscopic hardness

Per cent. Si .	0.01	2.0	7.5	15.0	16.0	93.4
Hardness .	24	56	74	64	60	74

Values were determined for intermediate alloys, but the results were considered to be unreliable. When free carbon does not separate, the addition of silicon hardens iron. P. Paglianti found Brinell's hardness increases approximately proportionally with the silicon content. L. Révillon observed that the tensile strength, *T*, and Brinell's hardness, *H*, of a sample of manganese silicon steel to be related as $H=0.389T$; and P. Paglianti gave $H=0.320T$. In 1887, W. A. Tilden, W. C. Roberts-Austen, and T. Turner found that with steels containing 0.10–0.50 per cent. of silicon, the **elastic limit** and **tensile strength** are increased while the **elongation** is diminished. R. A. Hadfield found that ingots could not be forged; he worked with steels having up to 4.90 per cent. of silicon, and carbon varying

from 0.14-0.26 per cent. T. Baker worked with 0.04 per cent. carbon and $7\frac{1}{2}$ per cent. silicon. L. Guillet worked with steels with varying manganese and carbon, and up to 5.12 per cent. of silicon. P. Paglianti worked with a carbon content of 0.10 per cent., manganese 0.22-0.60 per cent., and silicon up to about $6\frac{1}{2}$ per cent. G. A. Bisset said that silicon adds strength to iron comparable with the effect of carbon. T. D. Yensen also investigated the mechanical properties of the iron-silicon alloys. According to T. Turner, increasing the proportion of silicon increases the mechanical qualities of cast-iron until one or two per cent. of silicon has been added when further additions diminish these qualities—*e.g.* the maximum with the crushing strength is about 0.8 per cent.; with the tensile strength about 1.8 per cent.; and with the modulus of elasticity about 1.0 per cent. The general results of the observations show that silicon in quantities up to 4 per cent. increases the strength of steel proportionally with the amount added; if over 4 per cent. be added, the strength decreases rapidly probably owing to the formation of graphite, and the yield point corresponds with the breaking point. The ductility is but little affected by silicon below 2.5 per cent., but above this amount, the alloys become brittle, and with 4 per cent. or more, the elongation and reduction in area are nil. With 7 per cent. or more silicon, the alloys are not forgeable. Unlike carbon, silicon does not confer upon iron the property of becoming hardened when water-quenched. For alloys with 0.15 and 3.40 per cent. of silicon, T. D. Yensen gives respectively 18,500 and 58,000 lbs. per sq. in. for the stress at yield point; 37,000 and 67,500 lbs. per sq. in. for the ultimate strength; 56 and 21 per cent. for the elongation; and 90 and 28.5 per cent. for the reduction of area. P. Schübel gave for the **specific heat** of FeSi , 0.1476 between 18° and 193° ; 0.1504 between 18° and 300° ; 0.1532 between 18° and 399° ; and 0.1583 between 18° and 629° . Observations were also made by M. Padoa, and H. Schimpff. F. O. Osmond, and E. D. Campbell and W. E. Hartman have investigated the effect of silicon on the **heat of solution** of cast-iron in an ammoniacal soln. of cupric chloride. When the proportion of silicon approaches Fe_3Si , the product becomes insoluble in that menstruum. L. Troost and P. Hautefeuille, and H. von Jüptner have made thermochemical studies on siliceferous iron.

W. F. Barrett, P. Paglianti, C. F. Burgess and J. Aston, R. A. Hadfield and co-workers, T. D. Yensen, H. de Chatelier, W. Muthmann and co-workers, and W. Guertler investigated the **electrical resistance** of alloys of iron and silicon. M. von Schwarz found:

Per cent. Si	2.0	7.5	15.0	20.0	24.8	29.3	40.2
Sp. resistance $\times 10^4$	0.41	0.95	1.02	1.48	3.15	8.17	14.8 ohms

In general, silicon increases the electrical resistance of iron by 10-12 microhms per c.c. for each per cent. added. R. A. Hadfield and co-workers studied the **magnetic properties** of silicon-iron alloys. They found that alloys with 2.5 and 5.5 per cent. silicon had a higher maximum magnetic permeability and a lower hysteresis loss than pure iron. This led to the employment of silicon-steel for use in electromagnetic machinery, particularly in transformers. Numerous investigations have since been made on the magnetic properties of these alloys. T. Baker found:

Per cent. Si	0.02	1.02	2.90	4.80	7.47
Maximum induction ($H=20$)	16000	16200	15500	14750	14000
Permeability ($H=4$)	2325	2562	2750	2665	2937
Retentivity	8375	8000	7325	7290	9000
Coercive force	1.8	1.7	1.5	1.2	1.0
Energy dissipated per complete cycle	10550	8798	8081	6110	5613 ergs per c.c.

G. Dillner and A. F. Engström, unlike other investigators, found that silicon reduced the permeability and increased the hysteresis loss of sheet iron. E. Gumlich and P. Goerens, E. Gumlich and W. Rogowsky, P. Paglianti, S. Guggenheim, C. W. Heaps, J. Hopkinson, T. Murakami, T. D. Yensen, and others have investi-

gated this subject. Carbon in the form of graphite has a smaller damaging influence on the magnetic properties of iron than it has in the dissolved form, or combined as cementite. Silicon precipitates carbon as graphite, and this is an indirect reason why silicon exercises a beneficial effect on the magnetic properties of iron, since iron of a very high degree of purity still retains some carbon. The most favourable proportions vary between 2 and 4 per cent. The eddy-current losses decrease with an increase in the electrical resistance, and from this point of view the silicon content should be as high as possible without loss of the most favourable magnetic properties. T. C. MacKay studied the Hall effect in iron-silicon alloys.

A singular property of some samples of ferrosilicon, particularly alloys with approximately 50 per cent. silicon, is their tendency to spontaneous disintegration; *une explication très complète* of the phenomenon is not known. H. Heller said that the effect is likely to occur if over 33.3 per cent. of silicon is present, and that phosphorus and aluminium are directly responsible. It has been attributed to the presence of calcium silicide which is decomposed on exposure to humid air; but R. Frilley could not make the alloys spontaneously disintegrate in this way by purposely adding up to 10 per cent. of calcium. He found aluminium always present in the alloys which disintegrate. This was present either as aluminium silicide, or, as P. Lebeau suggested, as iron silicoaluminide. The disintegration is a serious inconvenience because of the difficulties which attend the use of the powder in some of its metallurgical applications; and also because the material *en poudre* exposes an enormously greater surface to the action of the air than what it does *en masse*. This means that oxidation, etc., by atm. air then becomes serious. To protect the material from oxidation, the lumps of 50 per cent. ferrosilicon are covered with a thin film of paraffin invisible to the naked eye. The resistance of ferrosilicon to chemical agents is to a large extent dependent on its composition. The 50 per cent. alloy is fairly resistant towards oxidizing agents, and this is also true of the different iron silicides. On the other hand, ferrosilicon is largely used in steel manufacture by virtue of its deoxidizing qualities. A fragment of 50 per cent. ferrosilicon is only superficially oxidized when heated in the blowpipe flame, and the film is probably nitride or carbonitride mixed with silica and iron oxide. J. J. Morgan founded a method for the determination of iron in alloys on the ready oxidizability of graphite and silicon; the silicon forms silica which remains as a residue when the oxidized iron is dissolved in acid. M. F. Matt found that ferrosilicon is but incompletely oxidized when heated in oxygen at 1100°. M. von Schwarz heated 50 per cent. ferrosilicon to 1100° in a stream of air for different periods of time, and found the percentage increases in weight to be:

Time in hrs.	7	14	21	25	32
Percentage increase. .	0.29	11.17	12.01	12.24	12.60

similarly in oxygen:

Time in hrs.	7	14	26	37	44
Percentage increase. .	11.26	13.64	16.14	18.00	19.02

Under certain conditions, some ferrosilicons—more particularly those ranging from 30–40 per cent., and from 47–65 per cent. silicon—under the influence of moist air are liable to evolve gases with dangerous and toxic properties. A number of fatalities have occurred during its transit on board ship, or during storage and use in factories. In some cases, passengers on ships or canal boats carrying ferrosilicon have died suddenly; in other cases, workmen have suffered more or less severely from the effects of breathing the fumes evolved from the material; and in a few cases, explosions have occurred spontaneously on handling the containing drums. On account of the accidents which have occurred from time to time, special restrictions are imposed on the transit and storage of ferrosilicon. A record of cases will be found in a report by S. M. Copeman and co-workers. A. Dupré and M. B. Lloyd showed that phosphine may be evolved by the action of water at ordinary temp.

P. Lehnkering also observed that air passed over ferrosilicon may give phosphine but no acetylene. He inferred that some calcium phosphide was present as an impurity in the ferrosilicon. A. W. Cronquist, C. E. Pellew, W. R. Smith, and P. Bruylants and H. Druyts observed phosphine and arsine in the gases. Hydrogen is also produced, but there is no evidence of the formation of silicane or of acetylene. H. W. Hake obtained similar results. According to N. S. Kurnakoff and G. Urasoff, an alloy with about 50 per cent. of silicon is sensitive to water and very dangerous. Alloys with 33.4–100 per cent. by weight of silicon furnish a solid soln. with 55.18–61.5 per cent. of silicon which solidifies at 1245° , and has been called *lebeaule*. The ternary solid soln. of lebeaule with phosphorus or aluminium are stable towards water; but the quaternary solid soln. of lebeaule with phosphorus and aluminium gives off phosphine when treated with water. Ferrosilicon with less than 33.4 per cent. of silicon, and containing γ -iron, will dissolve respectively 1.7 and 3.0 per cent. of phosphorus and aluminium. Calcium phosphide does not dissolve in liquid or solid ferrosilicon. N. S. Kurnakoff and G. Urasoff also studied the toxic properties of ferrosilicon.

R. Frilley found that hydrofluoric acid in the cold readily dissolves ferrosilicon with up to 50 per cent. silicon; hydrochloric acid attacks alloys with up to 33 per cent. silicon, but has virtually no action on alloys richer in silicon; nitric and sulphuric acids are without action; but a mixture of nitric and hydrofluoric acids attacks *très violemment* all the ferrosilicons. Fused alkali hydroxides or carbonates readily attack the iron-silicon alloys, and the attack is much more vigorous, and complete in the presence of potassium nitrate. With alloys containing over 50 per cent. of silicon, the attack by potassium or sodium hydroxide is extremely violent. Cold soln. of sodium hydroxide are without action on alloys with less than 50 per cent. silicon, but beyond that proportion, the attack becomes very vigorous, and a residue, completely soluble in hydrofluoric acid, remains. M. Wunder and B. Jeanneret found that hot phosphoric acid of sp. gr. 1.75 dissolves ferrosilicon, forming a clear liquid; any carbon present remains undissolved. U. Ehrhardt and G. Pfeiderer found crude tar oil containing phenol did not visibly attack ferrosilicon in 4 weeks' time.

Firma Biermann showed that ferrosilicon has an important influence in reducing the tendency of molten steel to become bubbly, "fiery," or frothy during casting. The way the silicon reduces the extrusion of gases from molten steel in the act of solidification has not been established. It is generally assumed that the silicon in steel decomposes iron or other oxides which may be present. The enhanced tensile strength conferred by low percentages of silicon has resulted in the use of silicon steels in making springs, etc. For the use of siliciferous iron in the manufacture of electromagnetic apparatus, *vide supra*. On account of the resistance of the silicon alloys to attack by acids, A. Jouve recommended vessels of ferrosilicon for the manufacture and conc. of sulphuric acid; and N. Terrisse and M. Levy, for acid-resisting alloys. A. Lissner also recommended these alloys as a substitute for platinum vessels in some industries. C. Höpfner recommended ferrosilicon as an electrode material for aq. soln. since it is more durable than carbon, and cheaper than platinum. The 25 per cent. alloy has been recommended for making statuettes, etc., since it polishes well. It is used as a master alloy in making silicon steels. It influences the properties of iron by controlling the condition of the carbon. V. Fuss studied the ternary system Si-Al-Fe.

C. Winkler³ heated nickel and silicon to a white heat and obtained a sintered not a fused mass; but he obtained a good alloy by reducing pickel oxide with aluminium, quartz, and cryolite. The regulus was contaminated with 12–15 per cent. of aluminium. R. Walter obtained nickel-silicon alloys by heating the component elements to a high temp.; and W. E. Gard obtained a white, homogeneous, fused, non-magnetic regulus in a similar way. E. Vigouroux found that when nickel is subjected to the action of silicon tetrachloride at a high temp. until the mass fuses and the loss in weight amounts to 30 per cent., the product consists of

nickel tetrakisilicide, Ni_4Si , which has a metallic appearance, is very brittle and crystalline, and is not attracted by a magnet. By the prolonged action of silicon tetrachloride on the lower silicide, it is converted into the **nickel hemisilicide**, Ni_2Si . The same compound is formed when nickel is heated with 10 per cent. of silicon in a current of hydrogen, the crystalline silicide is more fusible than the metal or silicon. Similar results are obtained by heating the silicon and the metal in a crucible in an oxyhydrogen furnace. Heating silicon with the metal oxide does not yield a pure product. The best results are obtained by heating the metal with 10 per cent. of silicon, in a carbon crucible in the electric furnace, until the greater part of the excess of the metal is volatilized. The product is treated with very dil. nitric acid. The hemisilicide is perfectly crystallized, and has a metallic appearance, and a steel-grey colour, and it is stable at the highest temp. The sp. gr. of the nickel hemisilicide is 7.2 at 17° . Fluorine attacks it with incandescence at the ordinary temp., and chlorine has the same effect at a red heat; bromine and iodine are less energetic in their action. Dry hydrogen fluoride and hydrogen chloride attack it at a red heat, and hydrogen bromide and iodide behave similarly. Hydrofluoric acid dissolves it readily, but the other haloid acids act very slowly; aqua regia, however, decomposes the powdered substance completely. Water has no action on the crystals, but water vapour attacks them at a dull red heat. Oxygen or air oxidizes the finely powdered silicide at a red heat. Soln. of alkali hydroxides are without effect, but fused alkali carbonates or mixtures of carbonates and nitrates decompose the silicide readily. W. Jenge studied the action of soln. of chlorides, bromides, iodides, nitrates, sulphates, sodium hydroxide, sulphuric acid, and hydrochloric acid on nickel silicides. The effects were similar to those obtained with cobalt silicides, but NiSi did not resist halogen ions. G. Tammann studied the chemical properties of these alloys.

M. A. Sanfourche discussed the limiting range of silicon in these alloys. W. Guertler and G. Tammann investigated the nickel-silicon alloys by thermal analysis, and controlled the results by microscopic examination of polished sections. They concluded that five silicides exist, Ni_3Si , Ni_2Si , Ni_2Si_3 , NiSi , and Ni_2Si_2 ; but they did not confirm the existence of the tetrakisilicide of E. Vigouroux. The f.p. curve of the system shows two maxima at 33.3 and 50 at. per cent. of silicon respectively, corresponding with nickel hemisilicide, Ni_2Si , and **nickel monosilicide**, NiSi , as well as three eutectic points at 20, 43, and 56 atomic per cent. of silicon respectively. From 0–11.6 and 27.6–33.3 per cent. of silicon, two series of solid soln. separate; if allowed to cool slowly, the sat. crystals interact below 1125° (in alloys containing 11.6–27.6 per cent. of silicon) with formation of **nickel trisilicide**, Ni_3Si ; the reaction is a reversible one. A third series of mixed crystals separates from 33.3–37.5 atomic per cent. of silicon; if the cooling is slow, **nickel ditritasilicide**, Ni_3Si_2 , is formed from these when the temp. falls below 830° . The existence of **nickel trihemisilicide**, Ni_2Si_3 , is formed on cooling by the interaction of silicon with the fused mass containing 59 atomic per cent. of the latter element. The alloys from 0–20 atomic per cent. of silicon are fairly tough; beyond this point they are brittle and easily powdered. Between the limits of 5 and 20 atomic per cent. of silicon, the alloys are fairly hard, but, contrary to the behaviour of carbon steel, the rapidly cooled alloys are much softer than those allowed to cool slowly. From 20 atomic per cent. of silicon, the hardness gradually decreases, reaches a minimum about 70 per cent., and beyond this point rapidly increases. Alloys containing more than 30 atomic per cent. of silicon are no longer magnetic. L. Baraduc-Muller made these alloys by reducing nickel oxide with carbon silicide, and he confirmed by thermal and microscopic observations the existence of Ni_2Si , Ni_3Si_2 , NiSi , and Ni_2Si_3 . R. Frilley found that alloys with below 5 per cent. of silicon have a grey colour, and have properties resembling steel with 1.4 per cent. carbon. Alloys with 5–20 per cent. silicon are whiter, and those with 15 per cent. of silicon have a brilliant faceted cleavage. Alloys with 20–35 per cent. silicon are less brilliant, and give a crystalline fracture showing ill-defined octahedral facets.

The crystals with the 32 per cent. alloy are acicular. The fracture of alloys with 35-40 per cent. silicon is matte and dull; alloys with over 50 per cent. silicon appear like fused silicon. M. François and C. Lormand examined the crystal structure. The following are selected from R. Frilley's determinations of the sp. gr., sp. vol., and mol. vol. of these alloys:

Per cent. Si	. 0	8.10	17.84	23.96	32.06	44.70	57.34	66.82'
Sp. gr.	. 8.4	7.77	7.30	6.68	5.73	4.60	3.93	3.50
Sp. vol.	. 0.110	0.129	0.137	0.160	0.174	0.217	0.254	0.286
Mol. vol.	. 6.98	6.94	6.73	6.95	7.56	8.57	9.34	9.80

The singularities in the sp. gr. curve correspond with Ni_2Si , NiSi , and Ni_3Si_2 ; the sp. vol. curve has singularities corresponding with Ni_2Si , and NiSi , but not Ni_3Si_2 ; and the mol. vol. curve has a singularity corresponding with Ni_2Si . There are no signs of Ni_4Si , Ni_3Si , or of Ni_2Si_3 on these curves. P. Schübel found for the sp. ht. of NiSi between 18° and 299° , 0.1367; 0.1380 between 18° and 421° ; 0.1420 between 18° and 501° ; and 0.1454 between 18° and 629° . For Ni_2Si , he gave 0.1197 between 18° and 202° ; 0.1226 between 18° and 294° ; 0.1245 between 18° and 410° ; and 0.1285 between 18° and 628° . R. Frilley found that hydrofluoric acid does not attack these alloys; hydrochloric acid does not attack the alloys with a high and a low proportion of silicon, but it does attack those with approximately 32 per cent. of silicon; sulphuric and nitric acids are without action; a mixture of hydrofluoric and nitric acids readily attacks these alloys; aqua regia dissolves in the cold alloys with less than 20 per cent. silicon; and none of the alloys is attacked completely by soln. of alkali hydroxides - cold or hot. Fused alkali hydroxides or carbonates decompose these alloys particularly in the presence of potassium nitrate. V. Fuss studied the ternary system Si-Al-Ni; and M. Plantsech, Si-Mo-Ni.

C. Winkler found cobalt and silicon behaved like nickel and silicon at a white heat. R. Walter made alloys by heating a mixture of cobalt and silicon to a high temp. According to E. Vigouroux, silicon tetrachloride is reduced by cobalt at the temp. of the electric furnace with the formation of cobalt chloride, which is volatile, and a residue of a cobalt silicide. At 1200° to 1300° , the reaction is complete, and ceases when the cobalt is converted into **cobalt hemisilicide**, Co_2Si , which has a sp. gr. 7.28 at 0° and 7.1 at 17° , and differs from H. Moissan's corresponding iron silicide in that it is not attracted by a magnet. E. Vigouroux also prepared the hemisilicide by a process similar to that employed for the corresponding nickel salt, and he found that the general properties were also similar. P. Lebeau prepared **cobalt monosilicide**, CoSi , in the form of prismatic needles by heating for 4-6 mins. in a carbon crucible placed in the electric furnace a mixture of copper silicide and metallic cobalt. The monosilicide melts at 1300° in a current of hydrogen, and has sp. gr. 6.30 at 20° . Cobalt silicide is converted into the fluoride with incandescence when gently heated in a current of fluorine; chlorine reacts only at a dull red heat; hydrogen fluoride or chloride decomposes the substance at high temp., yielding hydrogen and the corresponding haloid compounds of silicon and cobalt. Sulphur has no action on the compound at the softening point of glass; oxygen, nitrogen, ammonia, and steam, under these conditions, decompose the silicide only superficially; hydrogen sulphide, at high temp., gives rise to sulphides of cobalt and silicon. Nitric and sulphuric acids do not attack the silicide; it dissolves, however, slowly in aqua regia, and more rapidly in hydrochloric acid. Cobalt silicide is insoluble in dil. alkaline soln. but is decomposed by the alkali hydroxides, either fused or in conc. soln. Fused potassium nitrate and potassium hydrogen sulphate have no action on the substance; melted potassium carbonate attacks it only slowly. P. Lebeau also prepared **cobalt disilicide**, CoSi_2 , by heating cobalt mixed with an excess of silicon, or a mixture of cobalt, silicon, and copper silicide, in the electric furnace. It forms dark crystals with a bluish reflection, which often have an octahedral form and seem to belong to the cubic system. It has a sp. gr. 5.3 and hardness between 4 and 5. It is attacked by fluorine, with

incandescence, if gently heated, by chlorine at 300° , and by bromine and iodine at a dull-red heat. Sulphur has no action on it at the softening point of glass, oxygen attacks it superficially at 1200° , and nitric and sulphuric acids, conc. or dil., are without action. Hydrochloric acid, when conc. and boiling, attacks the silicide slowly, and hydrofluoric acid dissolves it rapidly; hot conc. soln. of alkali hydroxides attack it slowly, but the fused hydroxides decompose it rapidly. W. Jenge studied the action of soln. of chlorides, bromides, iodides, nitrates, sulphates, sodium hydroxide, sulphuric acid, and hydrochloric acid on cobalt silicides. Those with less than 32 per cent. silicon were readily attacked by acidic ions, while those with more silicon were resistant. That is, CoSi and the higher silicides behave like silicon, and the other silicides behave like cobalt. G. Tamman found that acids attack those silicides with cobalt in excess of $\text{Co} : \text{Si} = 1 : 1$ and alkalis those with the ratio $1 : 3$.

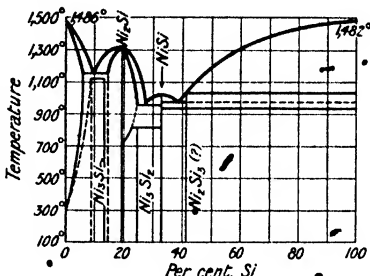

FIG. 21.—Equilibrium Diagram of Nickel-Silicon Alloys.

M. A. Sanfourche discussed the limiting range of silicon in these alloys.

K. Lewkonja studied the cobalt-silicon alloys by thermal analysis and controlled the results micrographically. The f.p. curve, Fig. 21, shows that the two elements are completely miscible in the liquid state, and in the solid state the miscibility is confined to alloys with less than 7.5 per cent. and more than 91 per cent. of silicon. Five compounds are shown on the diagram, cobalt hemisilicide, m.p. 1327° ; cobalt monosilicide, m.p. 1395° ; cobalt disilicide, m.p. 1277° ; **cobalt trisilicide**, CoSi_3 , m.p. 1310° ; and **cobalt ditritasilicide**, Co_3Si_2 , which

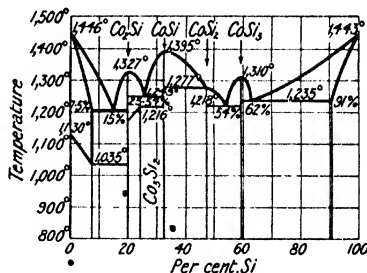

FIG. 22.—Equilibrium Diagram of the Cobalt-Silicon Alloys.

is formed in the solid state from the hemi- and mono-silicides. The range of existence of these compounds is shown in Fig. 22. Alloys with 0-19.5 per cent. of silicon are magnetizable. These alloys have cobalt in solid soln., and their magnetic intensity increases with the proportion of cobalt.

§ 14. The Silicides of the Platinum Family

J. J. Berzelius¹ stated that if silicon is ignited in a platinum crucible, the two elements do not react, but if silicon fluoride or potassium fluosilicate is reduced by potassium in a platinum crucible, the silicon penetrates into the platinum wherever the latter is touched by the potassium. J. B. J. D. Boussingault found that platinum fuses when embedded in charcoal powder, and exposed to the strongest heat of a forge, at the same time it takes up half per cent. of silicon; but if covered with lampblack containing no silica, fusion does not occur. C. Winkler, H. St. C. Deville, and P. Lebeau and A. Novitzky observed that silicon readily unites with platinum at a high temp., and a fusible silicide is formed. J. Königsberger and K. Schilling noted that the reaction begins as low as 400°, and at a red heat the reaction with crystalline silicon is quite fast. According to H. N. Warren, a silicide is readily obtained by heating amorphous silicon mixed with platinum black under a layer of potassium fluosilicate in a closed crucible. J. J. Berzelius, and J. B. J. D. Boussingault showed that platinum silicide is also formed when silica or a silicate is heated in contact with platinum under reducing conditions, say, in contact with carbon, not, said the latter, in consequence of the

formation of a carbide as assumed by H. V. Collet-Descotils. The absorption of silicon by platinum in contact with carbon in fireclay crucibles was noted by J. B. J. D. Boussingault, A. Ditte, L. Baraduc-Muller, etc. The formation of a fusible silicide explains how J. J. Precht was able to melt platinum in a blast-furnace. The vapour of silicon, said J. B. J. D. Boussingault, may be carried by the furnace gases to the platinum. P. Schützenberger and A. Colson, in the experiment cited in connection with the vaporization of silicon, said that nitrogen and probably also oxygen play a part in the transfer of the silicon to the platinum. M. Lapschin and M. Tichanowitsch found that if an electric current be passed through silica heated in a platinum crucible the metal will be perforated owing to the formation of a fusible silicide. J. B. J. D. Boussingault also found that when platinum is heated with silica in an atm. of hydrogen, some silicide is formed. C. G. Memminger ignited topaz in a platinum crucible placed inside a graphite crucible, and the platinum was converted into a brittle fusible substance with 1.61 per cent. of silicon. According to F. P. Miles, the conditions under which platinum silicide is formed are the presence of reducing gases such as carbon monoxide, of silicon tetrafluoride, and of a basic substance such as magnesia. The silicization of platinum resistance wire coiled round porcelain tubes to form electric tube furnaces, and heated in an atm. of hydrogen, has been discussed by L. Holborn and W. Wien, W. C. Heraeus, W. Ostwald and R. Küch—*vide infra*, action of reducing gases on silica.

According to C. Winkler, platinum which has absorbed 10 per cent. of silicon is greyish-white and fusible at a white heat. J. J. Berzelius found the sp. gr. to be 18.3; J. J. Precht, 17.7; and J. B. J. D. Boussingault, 17.5–20.5. According to the last-named, silicized platinum is hard enough to scratch iron and platinum, but it does not become harder by rapid cooling; it is brittle, it readily fractures under the hammer; it is still brittle at a red heat, and its ductility is not restored either by heating it in contact with air, or in contact with manganese dioxide. It dissolves in aqua regia more slowly than does platinum, and gelatinous silica separates. W. C. Heraeus found that the electrical resistance of platinum is increased by silicization.

Five definite silicides have been reported, but they may not be all chemical individuals since analysis is not a satisfactory test. For instance, C. Winkler reported that **platinum dodecasilicide**, PtSi_{12} , is formed, as a white crystalline mass, by melting platinum with an excess of silicon under cryolite. A. Colson reported **platinum hemisilicide**, Pt_2Si , to be formed when strips of platinum are packed in lampblack, and heated in a fireclay crucible. P. Schützenberger and A. Colson said that the reaction occurs at 1000° . P. Lebeau and A. Novitzky made it by heating platinum monosilicide with tin—*vide infra*; and E. Vigouroux, by heating platinum with 8–10 per cent. of silicon in a carbon-boat contained in a carbon-tube in an electric furnace. The hemisilicide is a white, crystalline, extremely hard, brittle solid, its sp. gr. at 18° is 13.8, it is capable of dissolving silicon, and is attacked, when hot, by chlorine, and by aqua regia; molten alkali hydroxides and hot aq. soln. of alkali hydroxides have but little action. A. Colson obtained a crystalline mass of what he regarded as **platinum ditritasilicide**, Pt_3Si_2 , by heating platinum with lampblack mixed with 60 per cent. of precipitated silica. The sp. gr. is 14.1; and the m.p. is near the squatting temp. of ordinary glass. A. Guyard made **platinum tritritasilicide**, Pt_4Si_3 , by heating a mixture of platinum dust with finely powdered crystalline silicon in the proportion of 2:1. Combination takes place at a red heat with some violence, some of the silicon gets thrown out of the crucible, and the remainder combines with the platinum, forming a compound which fuses at a somewhat higher temp. to a bright crystalline mass, metallic in appearance, and very brittle. E. Vigouroux made **platinum monosilicide**, PtSi , directly from its constituents with the silicon in excess, and also by melting a mixture of 24 grms. of platinum black, and 10.5 grms. of silicon in a magnesia boat in a stream of hydrogen for 30 mins. The excess silicon was removed by alkali-

lye, and the silica by hydrofluoric acid. P. Lebeau and A. Novitzky made the same compound by heating for half an hour to a high temp. pastilles composed of a mixture of very finely divided silicon and platinum sponge contained in a carbon crucible. It occurred in the form of a fused ingot with the appearance of silicon. An examination of a polished surface of the ingot reveals the presence of two substances, one of which is silicon, and can be removed by means of a dil. soln. of potassium hydroxide. The residue, which is soluble in aqua regia, has a composition corresponding with the formula SiPt . The same silicide is obtained by heating a mixture of equal parts of platinum and silicon for 5 mins. in an electric furnace. The silicide can be crystallized from fused silver silicide, the latter being afterwards dissolved by successive treatment with sodium hydroxide and nitric acid, and is then obtained in very fine prismatic crystals. The sp. gr. is 11.63 at 15°; and the m.p. about 1100°. This silicide is not attacked by hydrochloric, sulphuric, nitric, or hydrofluoric acid, but is attacked by hydrochloric acid and bromine, and is completely dissolved by aqua regia. When heated with tin, the product contains a mixture of free silicon with prismatic crystals and lamellæ. After washing with potassium hydroxide, this leaves a residue of the hemisilicide. E. Vigouroux found that when the monosilicide is heated with an excess of aluminium, an ingot is obtained which, after treatment with 10 per cent. hydrochloric acid, leaves a residue containing 91.2 per cent. of the silicon from the silicide in a free state. When the free silicon is removed by alkali-lye followed by treatment of the residue with aqua regia, a substance containing only 1.5 per cent. of combined silicon remains. Similarly, when heated with copper (10 grms.), the silicide (1 grm.) gives an ingot which is vigorously attacked by nitric acid (10 per cent.), leaving a residue consisting of platinum containing traces of combined silicon. By heating the copper silicide, SiCu_4 (12 grms.), with SiPt (3 grms.), a very brittle, grey ingot is formed, containing 20.6 per cent. of platinum, 67.2 per cent. of copper, and 12.20 per cent. of silicon. This is attacked with difficulty by nitric acid and by aqua regia, but is dissolved by a mixture of aqua regia and hydrofluoric acid. Finally, by heating the silicide, SiCu_4 (30 grms.), with platinum (10 grms.), a hard, greyish-white ingot is obtained, which is attacked by 5 per cent. nitric acid, leaving a black residue, from which a dense, grey substance soluble in aqua regia, and having the composition of **platinum copper silicide**, SiCu_2Pt , is isolated by levigation.

According to J. B. J. D. Boussingault,² when platinum, ruthenium, iridium, or palladium embedded in carbon in a siliceous crucible is heated to redness, the metal is silicized. Palladium, indeed, may take up nearly 4 per cent. of silicon. H. Moissan and W. Manchot prepared **ruthenium monosilicide**, RuSi , by heating a mixture of ruthenium powder and crystallized silicon in a carbon crucible in an electric arc furnace for two or three minutes. The product is crushed and treated with alkali, then with a mixture of hydrofluoric and nitric acids. The silicide is then left in the form of small, white crystals mixed with carborundum, which can be separated by flotation on methylene iodide. If some copper be added to the mixture, the silicide is ultimately obtained in a well-crystallized form. The silicide is white, and has a metallic lustre; at 4°, it has a sp. gr. 5.40 and is very hard. It volatilizes in an electric arc and is very stable. Fluorine easily attacks it, but it is only slowly attacked by chlorine. Bromine and iodine act on it slowly at 600°. When strongly heated, it burns in oxygen, and it is oxidized slowly by fused potassium chlorate or potassium dichromate. Sulphur vapour decomposes it at a red heat, and at the same temp. it is slowly attacked by fused sodium or magnesium. It is not attacked by boiling acids. Fused potassium hydroxide, carbonate, or nitrate only slowly decompose it; but when heated with a mixture of potassium hydrogen sulphate and potassium nitrate, it is decomposed and a per-ruthenate is formed. Potassium hypochlorite, which acts easily on ruthenium, has no action on the silicide. P. Lebeau and P. Jolibois found that when an intimate mixture of palladium and crystallized silicon is introduced into a porcelain crucible heated by means of a blowpipe, a contraction first occurs, and then, at 500°–600°,

a combination is produced, accompanied by a bright incandescence and sufficient elevation of the temp. to cause complete fusion. The fusion temp. of mixtures of silicon and palladium varies largely with the content of silicon. • With an increasing proportion of silicon, the m.p. falls, from 1587° for pure palladium to the minimum of 670°, corresponding with 6 per cent. of silicon; it then rises rapidly to the maximum 1400° for 11.76 per cent. of silicon (corresponding with **palladium hemisilicide**, Pd_2Si); the m.p. then again falls, reaching a second minimum of 750° for 16 per cent. of silicon, and afterwards rising to a second maximum of 990° for 21 per cent. of silicon (corresponding with **palladium monosilicide**, PdSi). With 25 per cent. of silicon there occurs another minimum at 825°, corresponding with a eutectic, and then the m.p. rises gradually to that of pure silicon. Mixtures containing less than 20 per cent. of silicon show a well-defined slackening in the rate of cooling, followed by a recalescence, the rise in temp. being sufficient to raise the mass to a bright red heat. The increase in incandescence so observed starts at a point in the mass and spreads in a manner similar to the crystallization of a supersaturated soln., and the similarity in the two phenomena is further shown by the fact that the recalescence is prevented by contact of the mixture at the commencement of solidification with a small fragment of a similar ingot previously prepared. The behaviour, on cooling, of mixtures containing more than 21 per cent. of silicon, indicates the presence of the eutectic (SiPd--Si). Ingots which have undergone recalescence have a different structure from the same products, tempered before the appearance of this phenomenon. In the latter case, two homogeneous constituents are always observed, and are very easily distinguished by oxidation. When, however, recalescence has occurred, the more oxidizable constituent is besprinkled with small crystals. The ingots corresponding with the compositions Pd_2Si and PdSi are both homogeneous, but only the latter silicide has been isolated in a crystalline form. When ingots containing above 60 per cent. of silicon are treated with dil. potash-lye, the free silicon dissolves, leaving small, very brilliant, bluish-grey fragments of the monosilicide of sp. gr. 7.31, which, when hot, is attacked by fluorine and chlorine; is superficially oxidized by oxygen at a dull red heat; is attacked by cold nitric acid and aqua regia; but not by hydrochloric or sulphuric acid; and is slowly attacked by alkali hydroxides.

§ 15. The Hydrogen Compounds of Silicon

Carbon is the dominating element in organic nature, while silicon unquestionably preponderates in the mineral world. The activities of carbon are most marked at comparatively low temp., silicon at high temp. For instance, carbon dioxide can displace silica at ordinary temp., and at high temp. silica can displace carbon

dioxide. Both the carbonates and the silicates are hydrolyzed at ordinary temp., so that aq. soln. of both salts give alkaline hydroxides—carbonic acid is also formed in the one case, and silicic acid in the other. Just as methane can be regarded as the starting-point of that branch of chemistry usually called *organic*, so the analogous silicon hydride can be regarded as the parent of a series of substances called *silico-organic* compounds. In 1863, F. Wöhler¹ emphasized the analogies between the carbon and the silicon compounds, and it would be easy to compile a long list of semblances and another list of dissemblances. For example, the compounds of silicon and hydrogen, the so-called **hydrosilicons**, are in some respects formally analogous with the hydrocarbons, but the analogies cannot really be pushed very far. D. I. Mendeléeff, and J. E. Reynolds argued in favour of the analogies; H. Moissan against. The latter has said:

Le carbone est seul. Il nous semble, en effet, qu'aucun autre corps simple ne peut lui être comparé, et l'immense développement de la chimie organique semble justifier cette séparation. Malgré il faut bien reconnaître que les composés dits organiques du silicium ne se rapprochent nullement par leurs propriétés des composés du carbone de même formule.

The number of hydrocarbons is enormous, very few hydrosilicons have been made; the former are usually very stable, the latter unstable. How far does the analogy between silicon and carbon go? Is it only a question of time and trouble for the development of a system of silicon chemistry analogous to that now established in carbon chemistry? Was H. Moissan correct in contesting any deep-seated resemblance between silicon and carbon? According to A. Stock, in spite of the agreement in the maximum valencies of the fundamental affinity units of these two elements, the two elements are distinctly dissimilar. He said that while the affinity of carbon is about equally strong for positive and negative non-metallic elements—hydrogen, oxygen, sulphur, nitrogen, and chlorine—there is an enormous difference between the positive and negative affinities of silicon. The affinity of silicon for oxygen is so predominant that practically all other silicon linkages are broken down by the action of cold water. A further difference is that while the four valencies are symmetrically distributed in carbon, they are not so in silicon. W. Barlow and W. J. Pope emphasized this from the point of view of the valency-volume theory.

The first four members of the homologous series of hydrosilicons, analogous with the methane series of hydrocarbons, have been isolated, and there are indications of the existence of the next two members. P. Lebeau,² and A. Besson have obtained evidence of a silicoethylene or silicoethene, $(\text{Si}_2\text{H}_4)_n$. J. Ogier has described a solid analogous with $(\text{Si}_2\text{H}_3)_n$; and C. S. Bradley, a yellow solid with a composition, $(\text{Si}_2\text{H}_2)_n$, analogous with acetylene. There is some doubt about the existence of the unsaturated hydrosilicons. The properties of the analogues methane and silicomethane are totally different. Several substitution products of the silicomethane series have been made in which aliphatic or aromatic carbon radicles have been introduced. F. S. Kipping has also established the existence of dextro- and levo-rotatory forms of phenylethylpropylbenzylsilicano-sulphonic acid:

The homologous series of saturated hydrides with the general formula $\text{Si}_n\text{H}_{2n+2}$, is formally analogous with the saturated $\text{C}_n\text{H}_{2n+2}$ series of hydrocarbons. For example:

	$\text{Si}_n\text{H}_{2n+2}$
Silicon tetrahydride, silicane, or silane	SiH_4
Disilicon hexahydride, silicoethane, or disilane	Si_2H_6
Trisilicon octahydride, silicopropane, or trisilane	Si_3H_8
Tetrasilicon decahydride, silicobutane, or tetrasilane	Si_4H_{10}
Pentasilicon dodecahydride, silicopentane, or pentasilane	Si_5H_{12}
Hexasilicon tetradecahydride, silicohexane, or hexasilane	Si_6H_{14}

On account of the formal analogy between methane, CH_4 , and silicon tetrahydride, SiH_4 , F. S. Kipping proposed the term *silicane* for the latter compound. A. Stock likewise used the termination *-ane* for this series, but he cut out a syllable so that the first member becomes *monosilane* or simply *silane*, and it has the composition SiH_4 ; *disilane*, Si_2H_6 ; etc. In A. Stock's nomenclature, the radicle SiH_3 , corresponding with methyl, CH_3 , is called *silyl*; the radicle Si_2H_5 , *disilyl*; etc. Two SiH_3 radicles are designated *bisilyl* or bis-silyl. The bivalent radicle SiO is called *silicyl*. The members of the homologous series Si_nH_{2n} , namely, Si_2H_4 , Si_3H_6 , Si_4H_8 , . . . , are distinguished by the termination *-ene*, as is also the case with the formally analogous ethene series of hydrocarbons, C_nH_{2n} . For example, Si_2H_4 is called *disilene*, Si_4H_8 , i.e. $\text{H}_2\text{Si}:\text{SiH}:\text{SiH}_2:\text{SiH}_3$ is *tetrasilene*; etc. Similarly, the members of the homologous series $\text{Si}_n\text{H}_{2n-2}$, namely, Si_2H_2 , Si_3H_4 , Si_4H_6 , . . . , are distinguished by the termination *-ine*, as is also the case with the formally analogous ethine series of hydrocarbons, $\text{C}_n\text{H}_{2n-2}$. Thus, silicoacetylene, Si_2H_2 , becomes *siline*; etc. The radicle Si_2H_3 is called *disilanyl*; silicochloroform, SiHCl_3 , in A. Stock's nomenclature, becomes *trichloromonosilane*; Si_3Cl_9 , *octochlorotrisilane* or *perchlorotrisilane*; $\text{SiH}_3(\text{OH})$, *monosilanol*; $\text{SiH}_2(\text{OH})_2$, *monosilandiol*; $\text{H}.\text{SiO}.\text{OH}$, or *silico-formic acid*, becomes *monosilanic acid*; and $(\text{SiO}.\text{OH})_2$, or *silico-oxalic acid*, becomes *disilanic acid*; etc. Compounds with both carbon and silicon have the prefix *silico-*; thus, $\text{SiH}_3.\text{CH}_2.\text{CH}_3$ is *monosilicopropane*; $\text{Si}(\text{C}_2\text{H}_5)_4$, *silico-nonane*, is called *tetraethylmonosilane*; and $\text{C}_3\text{H}_7.\text{SiO}.\text{OH}$, *silicobutyric acid*, is called *propylmonosilanic acid*.

The preparation of silane. The simplest compound of silicon and hydrogen, **silicon tetrahydride**, also called *silicane*, *monosilane*, or *silane*, SiH_4 , was discovered by H. Buff and F. Wöhler in 1857, and described in their memoir: *Ueber neue*

FIG. 23.—The Preparation of Impure Silane.

Verbindungen des Siliciums (Göttingen, 1857). They called it *Siliciumwasserstoffgas*—*silicuretted hydrogen*. The gas occurred among the products of the action of hydrochloric acid on the impure aluminium silicide which they had made; and it was also made by the electrolysis of an aq. soln. of sodium, ammonium, manganese, or ferrous chloride, using an alloy of aluminium and silicon for the positive pole. In 1858, F. Wöhler made the gas by the action of acids on manganese or magnesium silicide. The gas is spontaneously inflammable in air, and this property can be illustrated by the simple apparatus, Fig. 23, which is filled with dil. hydrochloric acid. Magnesium silicide is dropped into the funnel, and the bubbles of gas rising to the surface of the water in the dish ignite with a flash, and form rings of silicon dioxide.

The gas which is formed by the action of acids on magnesium silicide is a heterogeneous mixture. H. Moissan and S. Smiles say that the gas is essentially hydrogen mixed with 4.5 per cent. of silane, and some silicoethane which can be separated by condensation and subsequent fractional distillation. C. Somiesky found that the 13.7 grms. of silicon in 16.3 per cent. magnesium silicide gave:

Silicon as	SiH_4	Si_2H_6	Si_4H_{10}	Si_4H_{10}	Higher Hydrides
Grms. Si	1.2	0.93	0.52	0.30	0.22—Total 3.17 grms.

A. Besson also showed that the white solid which is formed is probably silico-oxalic acid. If phosphide or sulphide be present as an impurity in the silicide, the resulting gas will contain hydrogen phosphide or sulphide. H. St. C. Deville and H. Caron obtained the spontaneously inflammable gas by the action of acids on silicized zinc; H. Moissan obtained the gas by the action of acids on lithium silicide; and A. F. Holleman and H. J. Sluiper obtained the gas by the action of water on amorphous silicon prepared by using sodium as a reducing agent. The silicon hydride is supposed to have been derived from the sodium silicide present as an impurity.

The preparation of magnesium silicide for making the silicon hydrides has been previously discussed. A. Stock and C. Somiesky noticed that the reaction between the acid and the silicide occurs in two stages. In the cold, there is first a copious evolution of the silicon hydrides, and a brown flocculent substance is formed which decomposes slowly in the cold, and rapidly when warmed, forming the white solid. The yield of silicon hydride is largely determined by the conditions under which the acid attacks the silicide. Hydrochloric acid seems the most suitable because it introduces least disturbing side-reactions. The lower the temp., and the more rapidly the acid attacks the silicide, the better the yield of silicon hydrides, but, since the action of the acid is rather slow in the cold, a temp. of 50° was found to be most suitable for preparing silicon hydride. The yield is also better when the silicide is gradually added to the acid—not too dil.—rather than when the acid is gradually added to a mixture of the silicide and water. For the mechanism of the reaction—*vide* magnesium silicide. A. Stock and C. Somiesky's apparatus for gradually adding the silicide to the acid is illustrated by Fig. 24.

A represents a glass tube fitted with rubber-stoppers as shown. The stopper B is clamped to the tube to prevent it being forced out by the press. of the mercury. The side-tube F is connected to A by rubber-tubing, and it is fitted in conjunction with the mercury-holder H so that mercury can be introduced into A by opening the cock i, or removed by opening the cock g. A wooden disc K, fitted with a glass cylinder L, floats on the mercury in the tube A; and the wooden disc supports about 100 grms. of granular magnesium silicide contained between the cylinder L and the fall-tube C, which is 40 cms. long and 0.6 cm. bore. The other end of the tube C enters the gas-generating flask. The tube C is arranged so that the knocker, of an electric-ball connected with an accumulator, keeps the tube uniformly vibrating. This ensures a steady fall of the magnesium silicide down the fall-tube, as the mercury rising in C lifts the

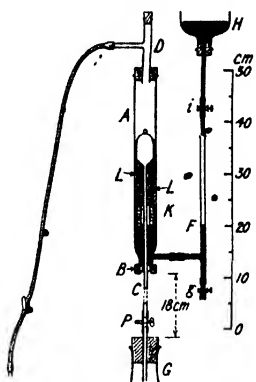

FIG. 24.—Apparatus for gradually Adding Magnesium Silicide to the Acid.

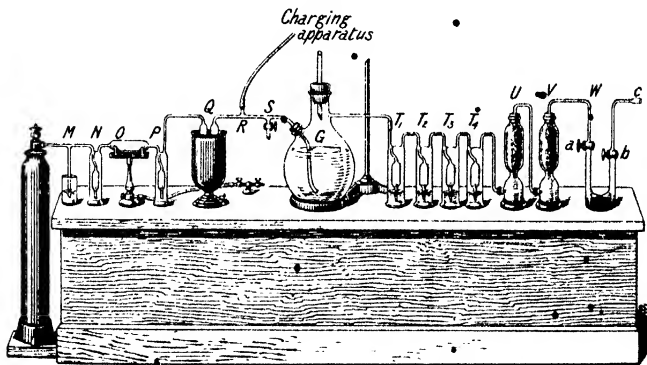

FIG. 25.—Apparatus for the Preparation of the Silicon Hydrides.

silicide above the upper level of C. The side tube of G is connected by means of a rubber tube with a T-piece fitted to an apparatus supplying hydrogen to the gas-generating flask, G.

A four-litre flask, G, Fig. 25, containing about 3 litres of a 10 per cent. soln. of hydrochloric acid is fitted to the charging apparatus, Fig. 24, and to the two trains of gas scrubbers shown

in Fig. 25. Hydrogen from a cylinder passes along a tube fitted with a safety-tube *M*; into a sulphuric acid washer *N*; thence through a tube *O* containing platinized asbestos at a dull red-heat; thence through another sulphuric acid scrubber *P*; and then through a U-tube *Q* of about 200 c.c. capacity, cooled with liquid air. The hydrogen then passes via the bifurcated tube *R* to the charging apparatus, and to the gas-generating flask *G*. A stoppered side-tube *S* allows air-free carbon dioxide to be passed through the apparatus if desired. The hydrogen inlet tube dips below the surface of the acid in the flask *G*; the exit tube is connected by means of rubber with four gas-washers, *T*₁, *T*₂, *T*₃, *T*₄, to remove hydrogen chloride; with a calcium chloride tower *U*; and with a similar tower *V* charged with phosphorus pentoxide and glass-wool. The gas condensing tube, *W*, is cooled by liquid air, and it is fitted with a vacuum stopcock *a*, and ordinary cock *b*, and an end *c* ground to fit the apparatus subsequently employed for fractionating the liquefied gas which collects in *W*. Hydrogen is passed through the whole of the apparatus before any silicide is added to the acid, and it is continued during the two hours which are occupied in adding 100 grms. of silicide to the gas-generating flask *G*. The part *W* is then removed; and the gases are driven from the apparatus by passing a stream of air-free carbon dioxide, via *S*.

The condensing tube is now connected with another apparatus fitted with tubes in which it is desired to collect the gas, and so arranged that any tube can be sealed off by the blowpipe flame, or by means of a stopcock. The apparatus is evacuated while the liquefied gases are still cooled by the liquid air. The liquid is then fractionated at the desired temp. The condensed liquid contains about a quarter of the silicon of the added magnesium silicide, in the form of the first six members of the homologous series $\text{Si}_n\text{H}_{2n+2}$; the remaining silicon appears as silico-oxalic acid. Assuming that the magnesium silicide contains the hexasilicide, the reaction involving the formation of the first member of the series is symbolized: $\text{Mg}_2\text{Si} + 4\text{HCl} \rightarrow 2\text{MgCl}_2 + \text{SiH}_4$.

The liquid obtained by cooling with liquid air the gases evolved when magnesium silicide is treated with acid, is distilled in vacuo between -125° and -120° , by using a bath of alcohol rendered viscid by cooling in liquid air. The operation requires 5–10 mins. The fraction can be again condensed by liquid air, and refractionated. The product is silane. The gas can be collected over mercury; 100 grms. of magnesium silicide give 1.6 grms. or 1100 c.c. of silane.

According to C. Friedel and A. Ladenburg, when silico-chloroform, SiHCl_3 , is treated with absolute alcohol, ethylsilico-orthoformate, $\text{SiH}(\text{OC}_2\text{H}_5)_3$, is produced. The product is also called *trithoxymonosilane*, and when treated with sodium, it furnishes silicane, and silicon tetrathoxide: $4\text{SiH}(\text{OC}_2\text{H}_5)_3 \rightarrow \text{SiH}_4 + 3\text{Si}(\text{OC}_2\text{H}_5)_4$. The function of the sodium is not known.

The trithoxymonosilane is added to a distillation flask—with a bulb 6 cms. diameter and neck 20 cms. long—provided with pieces of sodium. The mixture is gradually warmed over the free flame, and finally heated to the b.p., when about 2 litres of silane will be given off in about 2 hrs. The gas is collected over mercury. The reaction proceeds at lower temp. if potassium be used in place of sodium. Oxygen must be carefully excluded or an explosion may be produced. The gas is almost pure, but not quite free from other silicon hydrides.

O. Ruff and C. Albert found that a small proportion of silane is formed when silicochloroform is decomposed by a soln. of sodium hydroxide. A. C. Vournasos heated an equimolar mixture of anhydrous sodium formate and amorphous silicon, or, better, aluminium silicide, in a graphite tube at 1300° , and obtained a little spontaneously inflammable silicon hydride along with much hydrogen. He also made a little silicon hydride by heating a mixture of sodium formate, sodium hydroxide, and silicon chloride or sulphide in a stream of hydrogen.

As previously indicated, C. Friedel's attempts to induce the direct union of hydrogen and silicon at 1000° , or at the temp. of the electric arc, were not successful. E. Vigouroux, however, said that combination does occur at a white heat if a third element be present; and A. Dufour noted the presence of silane in the gas obtained when hydrogen is passed over silicon heated above its m.p. by the oxyhydrogen flame, or in the electric arc furnace. He said that if an electric discharge be passed through a tube filled with silicane, there is an immediate deposit of amorphous silicon, which, in about half an hour, disappears and is re-formed in the dark space about the cathode, even if the other parts of the tube are cooled to 80° —hence the phenomenon is not due to the distillation of silicon from the hot to the cold

parts of the tube. With arsenic hydride, under analogous conditions, the arsenic is distilled. The equilibrium conditions in the reaction $\text{Si} + 2\text{H}_2 \rightleftharpoons \text{SiH}_4$ were studied by H. von Wartenburg. He found that the decomposition is slow below 350° , and it is therefore necessary to employ a catalyst—*e.g.* finely divided nickel. If p_1 denotes the partial press. of the silane, and p that of the hydrogen, above 180° , the observed values agree with $\log (p_1/p^2) = 8700/4.57T - 1.75 \log T - 0.7$, where -8700 cal. represents the thermal value of the reaction $\text{SiH}_4 = \text{Si}_{\text{collid.}} + 2\text{H}_2$, -8700 cal. At 380° , for $p = \text{one atm.}$ the dissociation is almost complete, 99.6 per cent. At 180° , the observed degree of dissociation is 0.90, and at 260° , 0.93, the calculated values are 0.86 and 0.97 respectively. At temp. between 100° and 150° , the press. are higher than those corresponding with the above equation owing to some disturbing influence which H. von Wartenburg suggests may be the reaction: $2\text{SiH}_4 = \text{Si}_2\text{H}_4 + 2\text{H}_2$.

The properties of silane.—Silane is a colourless gas, and, according to A. Stock and C. Somiesky, a trace of the gas has a faint odour recalling that of stibine, but when more conc., the gas has a repulsive smell, and produces a headache. They found that 83.05 c.c. of the gas at 19° and 750 mm., or 76.62 c.c. at 0° and 760 mm., weigh 0.1103 grm.; consequently, 1 c.c. of the gas at n.p.t. weighs 1.440 mgrms. The density of the gas at 19° is 16.32; and the mol. wt., 32.29. The sp. gr. of the liquid at -185° is 0.68. A. O. Rankine and C. J. Smith found the viscosity of gaseous silane to be 0.0001078 at 8° ; 0.0001134 at 15° ; and 0.0001436 C.G.S. units at 100° ; W. Sutherland's viscosity constant (1, 13, 3) is 229; and the mean collision area of the mol. is 0.989×10^{-14} sq. cm. J. Ogier first liquefied the gas and found that it remains gaseous at 1° and 200–300 atm. press., and at 0° and 150–200 atm. press., but at -1° it liquefies at 100 atm. press.; at -5° , at 70 atm. press.; and at -11° , at 50 atm. press. The critical temp. is therefore near 0° . K. Adwentowsky and E. Drozdowsky gave -3.5° for the critical temp., and 47.8 atm. for the critical press. H. Moissan found the f.p. to be near -200° ; and A. Stock and C. Somiesky found a sharp m.p. for the white solid at -185° . R. Wintgen, and A. Stock and co-workers found the heat of vaporization to be 3.029 Cals., and the molar heat of vaporization at 0° to be 4246.7 cal.; 2782 cal. at 7° K.; and Trouton's constant, 17.3. The b.p. of the liquid is -112° at 760 mm., and the vap. press. of the liquid is:

	-160°	-150°	-140°	-130°	-120°	-118°	-114°	-112°
Vap. press.	11	41	102	230	470	530	590	760 mm.

R. Wintgen represented the vap. press., p , by the equation $\log p = 6.9961 - 662.6T^{-1}$. Comparing the more important constants of silane and methane:

	M.p.	B p. (760 mm.)	Sp. gr. liquid
Methane, CH_4	-184°	-160°	0.415 (-164°)
Silane, SiH_4	-185°	-112°	0.680 (-185°)

Silane is quite stable at ordinary temp.; nor is the dry gas decomposed on exposure to light. At a red heat, A. Stock and C. Somiesky found it to be decomposed into silicon and hydrogen; silane, however, is not decomposed so easily as the other silicon hydrides, since when the latter are sent at a low press. through a quartz tube at a dull red heat, some silane is formed; this is also the case when silicochloroform is heated: $4\text{SiHCl}_3 = \text{SiH}_4 + 3\text{SiCl}_4$. J. Ogier said that silane is completely decomposed into its constituents at 400° ; the reaction, however, is reversible as indicated by H. von Wartenburg—*vide supra*, where the observations of A. Dufour, and E. Vigouroux are described. J. Ogier found that silane is decomposed by the electric discharge, forming hydrogen, amorphous silicon, and a yellow solid which takes fire on percussion, or when heated in air; it takes fire in an atm. of chlorine; it is but little affected by water; and it is insoluble in alcohol, ether, benzene, chloroform, silicochloroform, and silicon tetrachloride. It contains 2.5 per cent. of silicon, and J. Ogier represented its composition by the

formula $(\text{Si}_2\text{H}_5)_n$; there is, however, nothing in the analyses to justify its recognition as a chemical individual. J. Ogier also found that if a mixture of equal vols. of silane and nitrogen be sparked, ammonia and a yellow solid are formed; the latter contains nitrogen, because it gives ammonia when treated with water. J. Ogier found the heat of combustion of one gram-eq. of silane in oxygen to be 324.3 Cals., which is less by 24.8 Cals. than the heat of combustion of its constituents; hence he argued that the heat of formation of silane from its elements is 24.8 Cals.—note H. von Wartenburg's measurement above—the heat of formation of methane is 22 Cals.

According to H. Moissan and S. Smiles, the spontaneous inflammability of silane is due to the presence of minute proportions of other silicon hydrides. C. Friedel and A. Ladenberg said that the purified gas at ordinary temp. and press. is not spontaneously inflammable, but it will inflame by slightly raising the temp., or lowering the press.; the purified gas inflames in air if bubbled through warm mercury, or if a hot knife-blade be held in the gas, bubbling through cold mercury. The gas inflames if air be bubbled into the purified gas at 100–150 mm. press. A. Stock and C. Somiesky said that small bubbles of the purified gas do not usually ignite in air, but larger bubbles sometimes fire spontaneously with the production of brown flakes; if other silicon hydrides are present, the gas always fires spontaneously in air. To avoid accidents, air should not be allowed to enter a vessel containing silane. K. Heumann said that the spontaneously inflammable gas can be preserved over mercury or over air-free water; but if the water has air in soln., the gas becomes foggy, and loses its spontaneous inflammability. A. Stock and C. Somiesky found that silane is slowly decomposed by water: $\text{SiH}_4 + 2\text{H}_2\text{O} = \text{SiO}_2 + 4\text{H}_2$. After 24 hrs.' exposure at 20° between 5 and 20 per cent. of the gas was decomposed; in about 30 days, decomposition was complete. K. Heumann said that each bubble of the spontaneously inflammable gas entering the atm. bursts explosively into flame, and the white flame emits clouds of silica in vortex rings—Fig. 25; silica and water are formed. The gas issuing from a tube into the atm. burns with a white luminous flame, which in sunlight casts a well-defined shadow. According to H. Buff and F. Wöhler, if cold porcelain be held in the flame, a brown or brownish-yellow film is deposited; and if the tube conveying the gas is heated, a dark brown mirror of amorphous silicon is deposited on the walls of the tube and the issuing gas is no longer spontaneously inflammable. A bubble of air, oxygen, or chlorine introduced into the gas causes a flash of light.

A. Stock and C. Somiesky have studied the oxidation of the silicon hydrides by air, and oxygen. They moderated the violence of the reaction by slowly adding the oxidizing agent to an excess of the hydride under reduced press. and between -70° and -140° . The products of the reaction consist of unchanged hydride (including SiH_4 during the oxidation of Si_2H_6), nitrogen (and argon) when air or artificial mixtures of nitrogen and oxygen are used (the oxygen is invariably consumed completely), a considerable quantity of free hydrogen, water, and, in certain cases, small quantities of volatile silicon compounds formed during the oxidation. In addition, there is formed a colourless, non-volatile residue which generally contains brown particles, and consists partly of compact crusts formed near the point of entry of the oxidizing agent, partly of a fog in the interior of the reaction vessel, and partly of a uniform, vitreous deposit on the whole wall of the vessel. The colourless components are readily dissolved by very dil. soln. of alkali, and appear to consist of substances such as polymeric prosiloxan, $(\text{SiH}_2\text{O})_2$, silicoformic anhydride, $[(\text{SiHO})_2\text{O}]_2$, etc.; the brown components contain silicon and possibly highly condensed silicon hydrides poor in hydrogen; they appear to be formed chiefly when the action is accompanied by considerable local heating and a deficiency of oxygen. In spite of variations in the temp. and in the degree of dilution of the oxygen, the reaction proceeds moderately uniform. The oxidation proceeds beyond the stage SiH_3OH , since the presence of $(\text{SiH}_3)_2\text{O}$ in more than traces could not have escaped detection. The main derivatives of silicon produced during

the oxidation are the polymeric forms of SiH_2O , OH.SiHO , SiO(OH)_2 , etc. The water is supposed to be produced from hydroxylated silicon compounds which become decomposed as the temp. is allowed to become atmospheric, thus $\text{SiH}_2(\text{OH})_2 \rightarrow \text{SiH}_2\text{O} + \text{H}_2\text{O}$. In those cases in which elementary silicon is deposited, a part of the liberated hydrogen is doubtless due to the thermal decomposition of silane. Its production is not due to a secondary hydrolysis of silane, or its primary oxidation products by water formed during the reaction; but it is rather a primary product of the oxidation: $\text{SiH}_4 + \text{O} = \text{SiH}_2\text{O} + \text{H}_2$; a reaction of this type is unusual and apparently due to the preponderating affinity of silicon for oxygen. The production of hydrogen accounts for the peculiarities observed during the combustion of silicon hydrides, which differs markedly in its violence from similar cases of spontaneous ignition such as the quiet inflammation of phosphorus hydride. The process consists of the following successive steps: inception of oxidation, liberation of hydrogen, formation of a mixture of oxygen and hydrogen, and ignition of the latter when the temp. has been raised sufficiently by the heat of the reaction.

The gas burns in chlorine or in chlorides, which easily part with their chlorine—e.g. carbonyl chloride, antimony pentachloride, tin tetrachloride, etc. According to R. Mahn, bromine forms with silane a mixture of $\text{Si}_2\text{H}_2\text{Br}_4$ and SiBr_4 ; G. Buchner said that silane mixed with hydrogen reacts with iodine, forming silicon tetraiodide, and silico-iodoform; iodine chloride reacts feebly and produces the hexachloride, Si_2Cl_6 , and phosphorus tri- and penta-chlorides, antimony pentachloride, and tin tetrachloride react similarly. T. Wilm and G. Wischin found that carbonyl chloride does not form an acid chloride, but parts with its chlorine. H. Buff and F. Wöhler observed no change when silane is brought in contact with nitrous oxide, nitric oxide, ammonia, dil. sulphuric or hydrochloric acid. A. Stock and C. Somiesky also observed no reaction between silane and dry ammonia, or conc. sulphuric acid. H. Buff and F. Wöhler stated that silane reacts with a soln. of cupric sulphate precipitating what they regarded as brown copper silicide, and possibly some copper and silica; that it does not react with soln. of lead acetate or hydrochloro-platinic acid; that it precipitates palladium free from silicon from soln. of palladous chloride; and that with soln. of silver nitrate, grey silver and black silver silicide are precipitated. G. Buchner stated that with neutral or acid soln. of silver nitrate, a yellowish-brown precipitate is first formed which then becomes black. He represents the reactions: $\text{SiH}_4 + 8\text{AgNO}_3 = \text{Ag}_4\text{Si}_4\text{AgNO}_3 + 4\text{HNO}_3$; followed by $\text{Ag}_4\text{Si}_4\text{AgNO}_3 + 4\text{H}_2\text{O} = 8\text{Ag} + \text{H}_4\text{SiO}_4 + 4\text{HNO}_3$. The more stable methane does not reduce like silane. Many of the less stable hydrides—like silicon hydride, hydrogen sulphide, and hydrogen iodide—reduce in virtue of the hydrogen liberated during their decomposition; other hydrides reduce by the direct oxidation of their elements. Thus, with arsenic hydride and silver nitrate, arsenious acid and silver are formed during reduction. H. Buff and F. Wöhler found that soln. of alkali hydroxides decompose the gas in the cold; and, according to A. Stock and C. Somiesky, soln. of alkali hydroxides decompose the gas more rapidly than does water; an alkali silicate is produced: $\text{SiH}_4 + 2\text{NaOH} + \text{H}_2\text{O} = \text{Na}_2\text{SiO}_3 + 4\text{H}_2$. At room temp. the reaction is complete in 2 hrs. with a 33 per cent. lye; and in 24 hrs. with a 10 per cent. lye.

A small quantity of an aq. soln. of potassium hydroxide was introduced into a eudiometer containing 2.8 c.c. of silane confined over mercury; 11.1 c.c. of hydrogen were formed. Hence, one vol. of gas gives 3.96 c.c. of hydrogen. Within the limits of experimental error, this agrees with the empirical formula SiH_4 ; and, since one litre of the gas at n.p.t. weighs 1.4538 grms., the mol. formula may be taken as SiH_4 .

A. O. Rankine and C. J. Smith discussed the electronic structure of silicane. With dry sodium or potassium hydroxide, a vigorous reaction occurs, and the surface of the hydroxide liquefies. Intermediate products are formed which in contact with water rapidly decompose into hydrogen and the alkali silicate. There is no apparent reaction with alcohol, ether, benzene, carbon disulphide, chloroform, or carbon tetrachloride. The organic liquids dissolve a little of the gas.

Silicoethane.—H. Moissan and S. Smiles³ found that when magnesium silicide reacts with hydrochloric acid, hydrogen containing about 5 per cent. of silicon hydrides is evolved. If the gases be cooled by liquid air or oxygen, the silicon hydrides solidify, and by allowing the solid to liquefy, and fractionating the liquid, **silicoethane**, *disilicane*, or *disilane*, Si_2H_6 , is obtained as a mobile, colourless liquid. P. Lebeau made the gas in a similar manner. H. Moissan obtained the same compound by the action of hydrochloric acid on lithium silicide. According to A. Stock and C. Somiesky, the liquid which remains after removing most of the silane from the gases obtained in their method of preparing silane (*q.v.*), when distilled between -120° and -115° for about 2 hrs. furnishes a mixture of silane and disilane. The silane can be removed by re-fractionation between -100° and -105° . The yield of disilane is 400 c.c., or 1.1 grms. per 100 grms. of magnesium silicide. A. Stock and C. Somiesky tried unsuccessfully to make silicoethane by the action of alkali metals on monochlorosilane. There are differences in the properties of the products as described by H. Moissan and S. Smiles, and by A. Stock and C. Somiesky, due, say the latter, and also P. Lebeau, to the contamination of the former's product with higher silicon hydrides. For instance, H. Moissan and S. Smiles say that silicoethane at ordinary temp. is a colourless liquid boiling at 52° ; but A. Stock and C. Somiesky say that it is a colourless gas, which furnishes a liquid boiling at a much lower temp. Silicoethane can be collected over mercury without perceptible decomposition; and it smells like silane, but is more repulsive. The density of the gas at 21° is 31.75 (theory, 37.1), and the mol. wt. is 64.0 (theory, 62.6); H. Moissan and S. Smiles obtained a density of 2.37 (air unity) at 100° . A. Stock and C. Somiesky found the sp. gr. of the liquid to be 0.686 at -25° ; and

	-118°	-110°	-90°	-61.15°	-46.8°	-37°	-22°	-15.7°
Vap. press.	1	2	10.5	81	180	290	550	725 mm.

R. Wintgen represented the results by $\log p = 72578 - 1133.67T^{-1}$. The b.p. is -15° at 760 mm.; P. Lebeau gave -7° , and H. Moissan and S. Smiles, $+52^\circ$, and they said that the m.p. is -138° , while A. Stock and C. Somiesky gave -132.5° . R. Wintgen, and A. Stock and co-workers found the molar heat of vaporization. The mol. heat of vaporization at 0° is 5443.1 cal., and at 5111 cal.; and Trouton's constant, 19.8. Disilane does not decompose at ordinary temp., but at about 300° , it is rapidly decomposed into a liquid and a brown solid which decomposes in contact with alkali-lye with the evolution of hydrogen. The decomposition of disilane at about 500° resembles the cracking of hydrocarbons; in addition to silicon, large vols. of silane are formed, the reaction being dependent on the reducing action of primarily liberated hydrogen on disilane. The higher hydrides are not produced in sufficient quantity to make the method a practicable process of preparation. At higher temp., the fission of the disilane occurs, and hydrogen predominates. Disilane is more stable than the corresponding diborane. H. Moissan and S. Smiles say that when the gas is sparked under reduced press. for 15 mins. it is decomposed into amorphous silicon and hydrogen; the silicon appears as a reddish deposit on the walls of the containing tube, and, added A. Stock and C. Somiesky, the decomposition by sparking is slower than is the case with diborane. Comparing the chief physical properties of silicoethane, diborane, and ethane:

	M.p.	B.p. (670 mm.)	Sp. gr. liquid
Ethane, C_2H_6	-171.4°	-89.3°	0.45
Diborane, B_2H_6	-169°	-87°	—
Silicoethane, Si_2H_6	-132.5°	-15°	0.69

H. Moissan and S. Smiles say that when silicoethane is exposed to air at ordinary temp., it inflames spontaneously, burning brilliantly and explosively; P. Lebeau said that the spontaneous inflammability is probably due to the presence of silicoethene, Si_2H_4 , but A. Stock and C. Somiesky state that highly purified silicoethane inflames spontaneously in air. The introduction of air into a flask containing silicoethane produces a vigorous explosion with the separation of white and brown

flecks. Like silicane, silicoethane is slowly decomposed by water at room temp.; in 24 hrs., 20-25 per cent. of the gas was decomposed, and in 13 days only 3 per cent. remained undecomposed. H. Moissan and S. Smiles say that silicoethane is slightly soluble in water, and is slowly oxidized thereby; and, added A. Stock and C. Somiesky, although the gas is not appreciably soluble in water, it is possible that the decomposition in contact with water occurs through the formation of an intermediate product soluble in water, because bubbles of hydrogen are developed in the water during the reaction. They also found that this reaction is largely conditioned by the alkalinity of the glass apparatus, for in quartz vessels, or with slightly acidified water practically no change takes place during several days. According to H. Moissan and S. Smiles, when the gas is bubbled through warm bromine-water, each bubble becomes coated with a layer of silica; nitric acid produces a similar effect; conc. hydrochloric acid is without action; and, added A. Stock and C. Somiesky, dry ammonia and dry hydrogen chloride have no appreciable action in a short time. Conc. sulphuric acid has no action during a short exposure, but, added H. Moissan and S. Smiles, the gas is dried, and it then explodes more violently in contact with air. Silicoethane explodes violently in contact with sulphur hexafluoride; and it is soluble in ethyl silicate. A. Stock and C. Somiesky found silicoethane to be fairly soluble in alcohol, and the soln. to develop slowly a gas, most of the silicoethane being given off unchanged when the alcoholic soln. is dil. with water. Silicoethane is readily soluble in benzene and carbon disulphide; if the silicoethane be mixed with hydrogen they can be separated by the latter solvent. If air has access to the soln. of silicoethane in carbon disulphide spontaneous ignition occurs. H. Moissan and S. Smiles found that silicoethane explodes violently when mixed with carbon tetrachloride, forming hydrogen chloride, carbon, and silicon; and A. Stock and C. Somiesky said that silicoethane reacts vigorously, often with incandescence, when in contact with carbon tetrachloride or chloroform, forming a brown solid. Silane and silicoethane thus behave differently in contact with these reagents. H. Moissan and S. Smiles found that silicoethane is attacked by a soln. of potassium hydroxide liberating hydrogen, and forming an alkali silicate; it reduces aq. soln. of ferric chloride to ferrous chloride, forming a brown precipitate insoluble in hydrochloric acid; a dil. soln. of indigo is decomposed, yielding a green precipitate; acid soln. of both potassium dichromate and permanganate are reduced, and in the latter case, brown manganese oxide is precipitated; soln. of silver nitrate, and auric chloride are reduced; and with mercuric chloride, mercurous chloride is formed. A. Stock and C. Somiesky said that with soln. of cupric sulphate, a copper hydride seems to be precipitated; and soln. of nickel sulphate, chromic chloride, and lead nitrate are not changed. The properties of silicoethane thus differs radically from those of ethane, but resemble in many respects those of silicane. The difference between the hydrocarbon and the hydrosilicon depend on (i) the smaller affinity of hydrogen for silicon than for carbon; and (ii) the readiness with which an oxygen atom can be interposed between the two silicon atoms, but not the two carbon atoms. It is, however, probable that silicoethane and ethane are constituted alike:

Silicopropane.—In A. Stock and C. Somiesky's method of preparing silane, and silicoethane, the residue remaining after the separation of most of the silicoethane from the condensed gas obtained from the action of hydrochloric acid on magnesium silicide, is fractionated at -60° , and re-fractionated at -70° . The product is **silicopropane**, *trisilicane*, or *trisilane*, Si_3H_8 ; the yield is 0.5 gm. for 100 grms. of magnesium silicide. Analysis corresponds with the formula Si_3H_8 . One c.c. of the gas at m.p.t. weighs 4.18 mgrms. The vap. density at 24° is 46.5 (theory,

46.1). The mol. wt. is 93.7 (theory, 93). The sp. gr. of the liquid is 0.743 at 0°/4°. The liquid freezes to a crystalline solid in liquid air; and it melts at -117.4°. R. Wintgen, and A. Stock and co-workers found the molar heat of vaporization to be 7.13 Cals. The mol. heat of vaporization at 0° is 5443.1 cal.; and Trouton's constant is 20.2. They also found:

	-70°	-50°	-30°	-10°	0°	15°	40°	52.6°
Vap. press. .	1	4	18	44	95	180	490	754 mm.

The vap. press., p , is represented by R. Wintgen by $\log p = 7.6764 - 1559.2T^{-1}$. The b.p. at 760 mm. is 53°. The vap. press. varies a little with the age of the sample on account of a slight decomposition. * Fresh samples at 0° have a vap. press. of 95.5 mm. Comparing the chief physical properties of propane and silicopropane:

	M.p.	B.p. (760 mm.)	Sp. gr. liquid
Propane, C_3H_8	below -195°	-45°	0.54
Silico-propane, Si_3H_8	-117.4°	+53°	0.743

Silicopropane is a light, mobile, colourless liquid much less stable than either silicane or silicoethane. After 18 days' storage at the room temp., a specimen, previously pure, contained less volatile silicon hydrides. Similar relations obtain between diborane and tetraborane. When heated, silicopropane decomposes into silicon and hydrogen, with silicane as an intermediate product. In air, silicopropane immediately inflames with a loud detonation and burns with a clear flame, forming brown and white solids. Silicopropane reacts slowly with water with the development of hydrogen: $Si_3H_8 + 6H_2O = 3SiO_2 + 10H_2$. After 24 hrs.' contact with water, 18 per cent. had decomposed so that the velocity of the reaction is nearly the same as with silicane and silicoethane. Likewise with soda-lye, silicopropane decomposed rapidly; with 33 per cent. lye, 90 per cent. had decomposed in 10 mins. and the calculated quantity of hydrogen: $Si_3H_8 + 6NaOH + 3H_2O = 10H_2 + 3Na_2SiO_3$, was obtained. Carbon tetrachloride acts more vigorously on silicopropane than on silicoethane. The explosive action noted by H. Moissan and S. Smiles, and A. Stock and co-workers was observed only in the presence of oxygen; the merest traces of oxygen suffices to induce the change. A. Stock and P. Stiebelier represent the reaction with chloroform by $Si_3H_8 + 4CHCl_3 = Si_3H_4Cl_4 + 4CH_2Cl_2$, and $Si_3H_8 + 5CHCl_3 = Si_3H_2Cl_5 + 5CH_2Cl_2$, at 50° in the presence of aluminium chloride. Small quantities of methane, and methyl chloride are also produced.

Silicobutane.—The liquid residue remaining after the removal of the silicopropane from the liquid condensed from the gases evolved by the action of hydrochloric acid on magnesium silicide, is distilled at a temp. of -25°, and the condensed product re-fractionated at -35°. The product is **silicobutane**, *tetrasilicane*, or *tetrasilane*; the yield from 100 grms. of magnesium silicide is 0.3 grm. Analyses agree with the formula Si_4H_{10} . The vap. density is 61.0 (theory for Si_4H_{10} , 61.2); the mol. wt. is 122.9 (calculated 123.3). One c.c. of the gas at 0° and 760 mm. weighs 5.48 mgrms. The sp. gr. of the liquid is 0.825 at 0°/4°. The m.p. of the solid is about -90°. R. Wintgen, and A. Stock and co-workers found the molar heat of vaporization to be 9.18 Cals.; and

	-30°	-20°	-15°	-5°	0°	+10°	20°	25°
Vap. press. .	0.8	1.0	2.8	5.8	7.8	14.0	24.0	33.0 mm.

At 0° the vapour press. of a freshly prepared sample is 7.5 mm. R. Wintgen represented the vap. press., p , by $\log p = 8.2479 - 2008.2T^{-1}$. The b.p. at atm. press. is 109°. The physical properties of *n*-butane, tetraborane, and silicobutane are:

	M.p.	B.p. (760 mm.)	Liquid sp. gr.
<i>n</i> -Butane, C_4H_{10}	-135°	0.6°	0.60
Tetraborane, B_4H_{10}	-112°	16°	—
Silicobutane, Si_4H_{10}	-90°	109°	0.825

Silicobutane is a colourless liquid, which very closely resembles silicopropane

in its properties. It decomposes fairly rapidly at room temp., and the vap. press. rises quickly on standing. The vap. changes the surface tension and meniscus of mercury. The gas decomposes into silicon and hydrogen when heated—silane is an intermediate product. In water, drops of the liquid acquire a turbid film, and hydrogen is slowly developed. It inflames with a loud detonation when exposed to the air. Silicobutane reacts like silicopropane with chloroform and carbon tetrachloride.

The liquid remaining after the removal of the series from silicane to silicobutane probably contains a small quantity of **silicopentane**, *pentasilicane*, or *pentasilane*, Si_5H_{12} , and a still smaller quantity of **silicohexane**, *hexasilicane*, or *hexasilane*, Si_6H_{14} . The former has a vap. press. of about 1.5 mm. at 0° , and the latter about 1 mm. No evidence of higher members of the series than Si_6H_{14} was observed. The penta- and hexa-silanes appear to behave like the lower homologue towards air, water, alkalis, etc., and also when heated. The higher members of the series are less stable to light and appear to decompose according to the scheme: $\text{Si}_5\text{H}_{12} \rightarrow 2(\text{SiH})_2 + \text{Si}_2\text{H}_6 + \text{SiH}_4$. The unsaturated hydride, $(\text{SiH})_n$, cannot be obtained in a volatile form of low mol. wt. If obtained by the autodecomposition of the silicoparaffins, by the action of the silent electric discharge on these compounds, by the action of acids on silicides, or by the action of sodium amalgam on silicoparaffins and their chlorides, it always appears in the solid, yellow, associated form, its composition varying between $(\text{SiH})_2$ and $(\text{SiH}_{1.3})_2$.

In general, it may be said that silicon has a much smaller affinity than carbon for hydrogen, and silane, the most stable member of the series, is much less stable than methane. The former decomposes at 300° – 400° , the latter at very much higher temp. The silane series of hydrosilicons are readily oxidized, and even take fire spontaneously in air; as also do other heavily hydrogenated compounds of silicon—e.g. monochlorosilane, SiH_3Cl . The members of the silicane series are decomposed by water, and more rapidly by soln. of alkali hydroxides. Similar remarks apply to the organic derivatives of the type SiHR_3 , where R denotes a hydrocarbon—alkyl or aryl radical; although C. Pape's⁴ tripropylsilane, $\text{SiH}(\text{C}_3\text{H}_7)_3$, is not attacked by alkali-lye. A few alkyl or aryl derivatives of the type SiHR_3 are known, but none corresponding with SiH_2R_2 or SiH_3R have been made. About fifty tetra-alkylsilanes have been made from silicon tetrachloride or silicochloroform by treatment with magnesium alkyl halides. They range from the simple tetramethyl silane, $\text{Si}(\text{CH}_3)_4$, to the complex $\text{Si}(\text{C}_2\text{H}_5)(\text{C}_3\text{H}_7)(\text{C}_6\text{H}_5)(\text{C}_7\text{H}_7)$. These compounds are inflammable liquids resembling ligroin or petroleum; their volatility differs but slightly from that of the corresponding hydrocarbons. They have been halogenated, sulphonated, nitrated, etc. A. Bygdén found the alkyl-silanes to be fairly stable liquids even in contact with water and alkali-lye; they show an asymmetric structure and optical activity; their rotatory power, however, is small in comparison with that of the corresponding hydrocarbons. The tetra-aryl derivatives of high mol. wt. are obtained more readily than the corresponding hydrocarbons—e.g. $\text{Si}(\text{C}_6\text{H}_5)_4$ is easily made, whereas M. Gomberg showed that triphenylmethane, $\text{CH}(\text{C}_6\text{H}_5)_3$, is formed under conditions where tetraphenylmethane, $\text{C}(\text{C}_6\text{H}_5)_4$, might have been anticipated. The fact that tetraphenylsilane, $\text{Si}(\text{C}_6\text{H}_5)_4$, and tetrabenzylsilane, $\text{Si}(\text{C}_7\text{H}_7)_4$, can be readily prepared, while tetraphenylmethane, $\text{C}(\text{C}_6\text{H}_5)_4$, can be made only with difficulty, and tetrabenzylmethane, $\text{C}(\text{C}_7\text{H}_7)_4$, is not known, is taken to show that while the affinity of silicon for hydrogen is less than that of carbon, the affinity of silicon for the hydrocarbon radicles is greater than that of carbon. The analogy between the silicon and carbon alkyl and aryl derivatives is perhaps not surprising when it is remembered that carbon *per se* exercises a preponderating influence on these compounds. Corresponding compounds with bismuth, tin, and lead are known.

* Compounds with chains of silicon atoms are usually far less stable than the corresponding carbon compounds, and this the more, the longer the chain. Several derivatives of silico-ethane are known—thus, A. Bygdén made *hexamethylsilico-*

ethane, $\text{Si}_2(\text{CH}_3)_6$; C. Friedel and A. Ladenburg *hexaethylsilicoethane*, $\text{Si}_2(\text{C}_2\text{H}_5)_6$; W. Schlenk and J. Renning, *hexaphenylsilicoethane*, $\text{Si}_2(\text{C}_6\text{H}_5)_6$; and G. Martin made *hexaethoxysilicoethane*, $\text{Si}_2(\text{OC}_2\text{H}_5)_6$. The more complex halides of silicon, or silicon compounds with hydrocarbon radicles, are rather more stable than the corresponding hydrogen compounds. The silicoethane derivatives with organic radicles, hexamethylsilicoethane, and hexaethylsilicoethane, are made from silicon hexachloride by treatment with the respective magnesium alkyl halides; and hexaphenylsilicoethane is made by the same reaction and by treating triphenylchlorosilane, $(\text{C}_6\text{H}_5)_3\text{SiCl}$, with sodium; while hexaethoxysilicoethane is made by treating silicon hexachloride with alcohol.

The unsaturated hydrosilicons.—The evidence of the existence of unsaturated derivatives of silicon—i.e. compounds with double-linked or triple-linked silicon atoms—is very doubtful. P. Lebeau⁵ reported that when the mixed gases formed by the action of hydrochloric acid and magnesium silicide are liquefied, and the liquid fractionated, the first product is a gaseous mixture of silane and silicoethane, and a colourless liquid. The liquid explodes violently in contact with air, and burns with a bright flame. He said that the probable formula is Si_2H_4 , corresponding with *silicoethene*, or *silicoethylene*. A. Stock and C. Somiesky consider this a mistake; they obtained no evidence of such a compound in their study of the products of the action of hydrochloric acid on magnesium silicide. This is confirmed by A. Besson and L. Fournier's failure to prepare the corresponding chloride, Si_2Cl_4 . L. Wöhler and F. Müller regarded the gas formed by the action of dil. acids on calcium monosilicide to be silicoethylene, formed in accord with the equation: $\text{Ca} : \text{Si} : \text{Si} : \text{Ca} + 4\text{HCl} = 2\text{CaCl}_2 + \text{H}_2 : \text{Si} : \text{Si} : \text{H}_2$. W. Schlenk, however, did make *diphenylsilicoethylene*, $(\text{C}_6\text{H}_5)_2\text{Si} : \text{CH}_2$, but the corresponding $(\text{C}_6\text{H}_5)_2\text{C} : \text{CH}_2$ has not been obtained. J. Ogier's analysis of the product obtained by sparking silicane corresponded with $(\text{Si}_2\text{H}_3)_n$, but he was probably dealing with a mixture. Similar remarks apply to C. S. Bradley's alleged synthesis of what has been called a polymerized *silicoacetylene*, $(\text{Si}_2\text{H}_2)_n$, by treating calcium silicide with hydrochloric acid. The yellow crystalline solid is not explosive, and is stable at ordinary temp.; when heated in air, it oxidizes to silica, and when heated in a closed tube, hydrogen is developed and silicon remains. A soln. of sodium hydroxide dissolves it with the development of hydrogen. The alleged *silico-acetylene* is not formed when strontium and barium silicides are treated in a similar way. The yellow solid is more probably analogous with F. Wöhler's *silicone*, $\text{Si}_3\text{H}_3\text{O}_2$ —*vide infra*. For $(\text{SiH})_2$, *vide supra*.

In 1824, J. J. Berzelius reported the formation of a solid silicon hydride by the action of potassium on silicon tetrafluoride, and subsequently washing the product with water, and cold aq. hydrofluoric acid to remove the silica. He assumed that the hydrogen liberated by the action of the excess of potassium on water reacted with the silicon, forming the hydride. He said the substance burns with great splendour when quickly heated to redness in air; and it burns still more brilliantly in oxygen; in neither case is the whole of the silicon oxidized because a protective layer of silica is produced. During the combustion, water is produced even when the hydride has been dried in vacuo at a temp. approaching redness. If this silicon hydride is heated in a covered crucible, a feeble flame is emitted when the cover is taken off. When slowly heated to incipient redness in an open crucible, and then to whiteness in a covered crucible, hydrogen is expelled, and a residuum of silicon, mixed with a little silica, remains. When treated with hot hydrofluoric acid, or potash-lye, a small quantity of silica is dissolved and hydrogen gas evolved. H. St. C. Deville doubted the existence of a hydrosilicon such as that described by J. J. Berzelius. More probably the product was related with F. Wöhler's oxyhydrides.

§ 16. Silicon Suboxides and Oxyhydrides—Siloxanes

The white product, resembling mother-of-pearl, obtained by the action of light and water on the yellow form of silicon was called by F. Wöhler¹ *leucone*—λευκός, white. The change occurs slowly in darkness. F. Wöhler assumed that the silicon decomposed the water, and formed leucone; his analyses of the product ranged between $\text{Si}_4\text{H}_2\text{O}_5$ and $\text{Si}_4\text{H}_3\text{O}_5$. O. Hönigschmid's analyses of the white product obtained by the action of air and light as well as of water on silicon, after washing with alcohol and ether, and drying in vacuo over sulphuric acid, corresponded with $\text{Si}_3\text{H}_3\text{O}_4$; it had a similar crystalline form to calcium silicide. A. Geuther made a substance with a composition $\text{H}_2\text{Si}_3\text{O}_5$, by the action of hydrochloric acid on magnesium silicide. A. Michaelis considered it to be silicoformioanhydride, C. Winkler supposed it to be different. D. I. Mendeleeff gave SiH_4O_3 for the composition of leucone, and he regarded it as *trihydroxysilane*, $\text{SiH}(\text{OH})_3$, which he assumed to be the first product of the hydrolysis of trichlorosilane or silicochloroform, SiHCl_3 , a reaction which he symbolized: $\text{SiHCl}_3 + 3\text{H}_2\text{O} = \text{SiH}(\text{OH})_3 + 3\text{HCl}$. He continued: This hydrate, like the corresponding hydrate of phosphorus or carbon, does not remain in this state of hydration, but loses a portion of its water. The carbon hydrate, trihydroxymethane, $\text{CH}(\text{OH})_3$, loses water and produces formic acid, H.CO.OH ; but trihydroxysilane loses a still greater proportion of water and leaves $\text{Si}_2\text{H}_2\text{O}_3$, which must be an anhydride, two remaining hydrogen atoms being left from the silane:

This product is, therefore, called **silicoformic anhydride**, HSiO.O.OSiH . H. Buff and F. Wöhler discovered this compound in 1857; they showed that it is formed, as a voluminous white powder when silicochloroform, silicobromoform, or siliciodoform is hydrolyzed by water at 0° : $2\text{HSiCl}_3 + 3\text{H}_2\text{O} = 6\text{HCl} + \text{Si}_2\text{H}_2\text{O}_3$. C. Friedel and A. Ladenburg recommend the following mode of preparation:

Silicochloroform, boiling between 34° and 35° , is gently distilled into water at 0° . The end of the tube dipping in water has a funnel-shaped end so as to prevent its being blocked by the formation of the solid. As soon as the first bubble has traversed the liquid, the white insoluble compound appears; and when the operation is ended, the product can be readily separated by filtration, washed with iced-water, pressed between folds of filter-paper, and dried in *vacuo* over sulphuric acid. After these operations, the product can be dried at 150° without decomposition.

L. Gattermann prepared this compound in a similar manner, but washed it with iced-water, alcohol, and ether. C. Winkler said that the compound is formed by the action of a soln. of ammonium chloride on magnesium silicide—the product is coloured brown owing to the presence of amorphous silicon. F. Wöhler showed that this substance is probably present in the residue which remains after dissolving grey cast-iron, or manganese silicide in hydrochloric acid. According to L. Cambi, silicoformic anhydride is produced when silicon sulphide, SiS , in small pieces is treated with iced-water free from air in an atm. of hydrogen. The product can be washed with cold water, alcohol and ether. He said that *silicoformic acid*, H.SiO.OH , is probably formed first: $\text{SiS} + 2\text{H}_2\text{O} = \text{H}_2\text{S} + \text{H.SiO.OH}$, and added: The formation of silicoformic acid is analogous to that of formic acid, which can be obtained from chloroform, carbon monoxide, or compounds containing bivalent carbon, such as the carbylamine derivatives, $\text{C}:\text{NR}$; this analogy can be extended to the corresponding germanium compounds.

H. Buff and F. Wöhler found that silicoformic anhydride is a voluminous, amorphous, white powder which sinks in ether, and floats in water. It is not changed at 300° , but when heated more strongly, hydrogen and silane are evolved, and a mixture of brown amorphous silicon and silica remains. L. Cambi said that in *vacuo*, at 400° , it splits up into hydrogen, silicon, and silica. O. Honigschmid said that when leucane is heated in *vacuo*, the brownish-yellow crystalline residue which remains has the composition of *silicon tetratritoxide*, Si_3O_4 , and it dissolves in alkali-lye, and in hydrofluoric acid with the evolution of hydrogen. H. Buff and F. Wöhler stated that when silicoformic anhydride is heated in air, it glows with a phosphorescent light, and is finally oxidized to silica; when heated in oxygen, it burns brilliantly; when heated in hydrogen, the evolved gas contains silicon hydride; it is not changed by conc. nitric acid or the other mineral acids, but with hydrofluoric acid, it is vigorously dissolved, and hydrogen, etc., is evolved. L. Cambi said that water oxidizes it at ordinary temp. and hydrogen is evolved: $\text{Si}_2\text{H}_2\text{O}_3 + \text{H}_2\text{O} = 2\text{SiO}_2 + 2\text{H}_2$. H. Buff and F. Wöhler found that aq. ammonia, and alkali hydroxides or carbonates dissolve it giving off hydrogen, and forming an alkali silicate: $\text{Si}_2\text{H}_2\text{O}_3 + 4\text{KOH} = 2\text{K}_2\text{SiO}_3 + \text{H}_2\text{O} + 2\text{H}_2$. D. I. Mendeléeff said: "The compound has no acidic properties and there are no acid hydrates of silicon, corresponding with formic acid, which give salts when acted on by alkalis. It must not, however, be forgotten that when formic acid is heated with an alkali, a carbonate and hydrogen are formed: $\text{CH}_2\text{O}_2 + 2\text{KOH} = \text{K}_2\text{CO}_3 + \text{H}_2\text{O} + \text{H}_2$. Consequently, a similar decomposition is accomplished with silicoformic anhydride as with formic acid, only at the ordinary temp." L. Cambi said that silicoformic anhydride is a strong reducing agent. L. Gattermann found that permanganate soln. are reduced by it, but not chromic acid; and H. Buff and F. Wöhler obtained

with silver nitrate soln., a brown substance which, when treated with aq. ammonia, forms silver silicate.

H. Buff and F. Wöhler examined the liquid which remained after the separation of silicoformic anhydride by filtration. On standing, or when rapidly heated, or when ammonia is added, hydrogen is evolved. The liquid has strong reducing properties, for it separates sulphur from sulphur dioxide; acidified soln. of selenic or telluric acid deposit selenium or tellurium; mercuric chloride gives mercurous chloride or mercury; potassium permanganate soln. are decolorized; soln. of auric chloride give the metal; soln. of palladous chloride give a black powder; soln. of potassium cupric oxide give hydrated cuprous oxide; and silver soln. give first silver chloride, then a dark brown precipitate which is converted by ammonia into silver silicate. Soln. of chromic acid, indigo, platinum, and iridium salts are not changed.

C. Friedel and A. Ladenburg found that when hexabromosilicoethane, Si_2Br_6 , is treated with iced-water, hydrogen is evolved, and a white powder is deposited which when washed with water at 0° , and dried at 100° , has the composition: $\text{Si}_2\text{O}_2(\text{OH})_2$; it is called **silico-oxalic acid**. The air-dried powder has the composition: $(\text{SiOOH})_2 \cdot 2\text{H}_2\text{O}$. They also made it by the action of hexafluorosilicoethane, Si_2F_6 , on absolute alcohol, the ethyl iodide formed at the same time being removed by distillation. L. Troost and P. Hautefeuille obtained the same product by the action of water on hexachlorosilicoethane. L. Gattermann and K. Weinlig made it by exposing purified hexachlorosilicoethane in a platinum dish, cooled with ice, to the moisture of the air until it was converted into a solid, white mass. It was then allowed to remain over lime as long as hydrogen chloride was given off. The product contained 97 per cent. of silico-oxalic acid. The formal relationship between oxalic and silico-oxalic acids is illustrated by the formulæ:

C. Friedel and A. Ladenburg explain the formation of silico-oxalic acid by supposing $\text{Si}_2(\text{HO})_6$ to be first produced, and to become $\text{Si}_2\text{O}_2(\text{HO})_2$ by the loss of $2\text{H}_2\text{O}$. Although this substance is the chemical analogue of oxalic acid, it has no acid functions; it passes, even the most dil., decompose it with evolution of hydrogen, just as oxalic acid under certain conditions is decomposed by potassium hydroxide. Silico-oxalic acid is said to be a white amorphous powder; and when heated in air or oxygen, it decomposes with incandescence, leaving a residue of silica in proportions agreeing with $2(\text{SiOOH})_2 + \text{O}_2 = 2\text{H}_2\text{O} + 4\text{SiO}_2$. L. Gattermann and K. Weinlig said that when heated in a test-tube, it decomposes violently with feeble detonation and the evolution of hydrogen. It also explodes when rubbed with a hard substance. When heated with bases, it develops hydrogen: $(\text{SiOOH})_2 + 4\text{KOH} = 2\text{K}_2\text{SiO}_3 + 2\text{H}_2\text{O} + \text{H}_2$. L. Troost and P. Hautefeuille showed that silico-oxalic acid is a reducing agent; permanganic acid is rapidly reduced, and chromic acid slowly. Cold aq. soln. of selenic acid and of auric chloride are not reduced. Conc. nitric acid is absorbed by silico-oxalic acid, and is not removed by washing or drying in vacuo; and is given off only when heated near the decomposition temp. of silico-oxalic acid. Hydrochloric and sulphuric acids are not taken up in the same way.

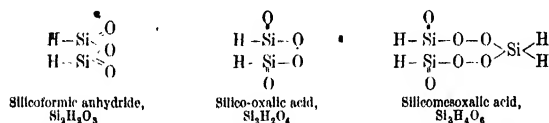

According to L. Gattermann and K. Weinlig, when octochlorosilicopropane, Si_2Cl_8 , is rapidly decomposed by water, it forms an insoluble acid which is probably **silicomexoxalic acid**, $\text{HO}_2\text{SiSiSiO}_2\text{OH}$. L. Gattermann and E. Ellery made this acid by exposing octochlorosilicopropane in a platinum dish, at 0° , to atm. air. Hydrogen chloride is evolved and silicomexoxalic acid remains. The formal analogy with the corresponding carbon compound is illustrated by the formulæ:

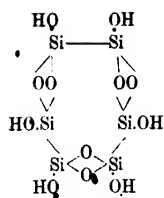

Silicomesoxalic acid is a white powder which does not dissolve in cold water, but is decomposed by hot water giving rise to silica and hydrogen. The acid when dry is extremely unstable and decomposes more violently than silico-oxalic acid. The decomposition often occurs spontaneously and with incandescence. The acid has strong reducing properties, and rapidly reduces a warm alkaline soln. of potassium permanganate.

It is doubtful if silico-oxalic acid and silicomesoxalic acid possess the simple mol. formulae which characterize their organic namesakes. They are amorphous, non-volatile, and insoluble in water. Silico-oxalic acid decomposes when warmed; and silicomesoxalic acid is liable to decompose explosively with the evolution of hydrogen. D. I. Mendelëff says that these compounds probably form silica and silicon hydride which decomposes into silicon and hydrogen just as phosphorous and hypophosphorous acids decompose into phosphoric acid and phosphine under similar circumstances. When heated in air they burn, forming silica. They are not attacked by acids, and with alkalis they give off hydrogen and form a silicate. G. Martin has brought forward some evidence to show that in the presence of attached oxygen atoms, say H.O.H- or potassium hydroxide—two directly linked silicon atoms, $\equiv\text{Si}-\text{Si}\equiv$, are severed with the liberation of hydrogen: $\equiv\text{Si}-\text{Si}\equiv + \text{H.O.H} \rightarrow \text{H}_2 + \equiv\text{Si}-\text{O}-\text{Si}\equiv$; and thus one directly linked pair of silicon atoms corresponds with the evolution of one mol. of hydrogen. This agrees with the action of aq. alkalis on, say, hexaethoxydisilane, $\text{Si}_2(\text{OC}_2\text{H}_5)_6$. Unlike the silicic acids, all the (presumably) hydroxyl groups of silico-oxalic and silicomesoxalic acids are retained in vacuo, over sulphuric acid at 15° , or steam at 100° . G. Martin considers that the greater stability of silicoxalic acid "proves that the silicon atoms which are directly united retain hydroxyl-groups much more tenaciously than do silicon atoms which are united through oxygen atoms," as is presumably assumed to be the case with silicic acid.

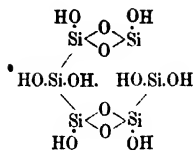

It has been assumed that the easy decomposition of the silico-oxalic acids, their disinclination to form salts, and the evolution of hydrogen when they are treated with potassium hydroxide, show that the hydrogen is probably united directly with the silicon and not indirectly through hydroxylic oxygen as in the case of the silicates. Consequently, the analogy with the oxalic acids, suggested by the names, does not hold good. Formic acid, however, when heated with alkalis does evolve hydrogen: $\text{HCOOH} + 2\text{KOH} = \text{K}_2\text{CO}_3 + \text{H}_2\text{O} + \text{H}_2$, and hence the so-called silico-formic anhydride is probably the anhydride of an analogous acid, $\text{H}(\text{SiO})\text{OH}$. The graphic formulae can therefore be represented, *pro tempore*, as:

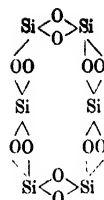

G. Martin argued that (1) the mode of formation of silico-oxalic acid by the hydrolysis of hexaethoxydisilane, $\text{Si}_2(\text{OC}_2\text{H}_5)_6$, shows that it contains the chain $-\text{Si}(\text{OH})-\text{Si}(\text{OH})-$; and that the mode of formation of silicomesoxalic acid by the hydrolysis of the octochlorotrisilane, Si_3Cl_8 , shows that this acid contains the group $-\text{Si}(\text{OH})-\text{Si}(\text{OH})_2-\text{Si}(\text{OH})-$. (2) It is necessary to explain why the action of ammonia gives only one kind of silica by assuming that (i) at least three mols. of hydrolyzed hexachlorodisilane are linked together by oxygen atoms when silicoxalic acid is formed; (ii) at least two mols. of hydrolyzed octochlorotrisilane are similarly linked together to form silicomesoxalic acid; and (iii) when the two silico-oxalic acids are treated with ammonia, each ring loses its hydroxyl groups to form a cyclic or ring compound involving at least 6SiO_2 , which is supposed to represent the mol. of silica. The hypothetical relation between the three compounds in question is illustrated graphically:

Silico-oxalic acid

Silicomeso-oxalic acid

Silica

Granting that these formulæ for silico-oxalic and silicomeso-oxalic acid are valid, it cannot be safely assumed that because silicic acid is produced by these reactions, the commonly accepted formulæ are erroneous. The silica actually produced may be the only form which is stable under the conditions of the experiments just as when water is liberated from all sorts of complex reactions, the equilibrium product is always the same for the same conditions of temp. and press. In order to maintain the proposition that silica is a hexadic ring, it would be necessary to assume a complex change when silica is liberated from hexachlorodisiloxane, etc. In the absence of the mol. wt. and more precise information concerning these and other compounds of silicon, it is possible to weave wonderfully ingenious and subtle patterns, with gossamer threads which have far too fine a texture to bear contact with harsh material facts.

F. Wöhler designated by the term **silicone** a product which he obtained by the action of conc. hydrochloric acid upon calcium silicide. The following is the mode of preparation:

Calcium silicide in fragments was treated with hydrochloric acid in a vessel surrounded by cold water. Hydrogen was evolved and the calcium silicide gradually converted into silicone. The mixture was left for several hours in a dark place; and agitated until the evolution of gas had ceased. The mixture was diluted with six or seven times its vol. of water, and filtered while protected from light. The product was washed, pressed between filter-paper, and dried in darkness in vacuo over sulphuric acid.

D. I. Mendeleeff called it *chryscone*—*χρῑςῑνος*, golden. Analysis showed that the alleged silicone contains both hydrogen and oxygen, corresponding approximately with the formula $\text{Si}_2\text{H}_3\text{O}_2$. O. Boudouard obtained a similar product by the action of hot hydrochloric acid on silicon-steel. O. Hönigschmid said that the crystals are dark yellow plates, pseudomorphs after calcium silicide, and that they have a smaller sp. gr. than silicon. The crystals are bleached white by a few minutes' exposure to direct sunlight, and they are gradually decolorized on exposure to diffuse daylight, probably by oxidation. When heated in vacuo, or in an atm. of hydrogen, the product gives off hydrogen and furnishes a greyish-black substance. F. Wöhler said that when heated in a tube to 100° , it develops hydrogen and leaves a mixture of silicon and silica; at 190° in a sealed tube, it is converted into hydrogen and silica. O. Boudouard said that it decomposes if heated above 200° , and that decomposition is complete at 450° ; and E. Donath, that silicone is converted into leucone by heat, and light. With water, hydrogen is evolved, and the product becomes white; the reaction is slow in darkness, rapid in light. E. Donath and E. Lissner said that the compound is insoluble in water, alcohol, silicon tetrachloride, phosphorus trichloride, and carbon disulphide. When heated at bright redness in a stream of dry chlorine or hydrogen chloride, it is decomposed with an explosion. It is decomposed very slowly by hydrochloric acid; and fuming nitric acid oxidizes it with incandescence. If suspended in water and then treated with nitric acid, it decomposes with the evolution of nitrogen oxides. The reaction is slow at first, but progresses rapidly later on. The silicone is at the same time oxidized to silicic acid. According to O. Hönigschmid, fuming nitric acid oxidizes silicone with incandescence. Conc.

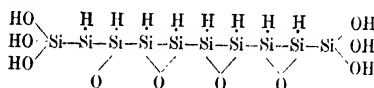

sulphuric acid has no action. The dil. mineral acids act like water. S. Tamaru found that the coloured tabular crystals become white after prolonged contact with hydrofluoric acid. Conc. hydrochloric acid acts similarly.

The fact that the hydrogen in F. Wöhler's product behaves like that in silicon hydride led O. Hönigschmid to assume that the hydrogen is attached directly to the silicon and not to the oxygen. According to O. Hönigschmid, alkali hydroxides or carbonates, ammonia, and pyridine decompose the silicone with the evolution of hydrogen: $2\text{H}_3\text{Si}_3\text{O}_2 + 12\text{KOH} + 2\text{H}_2\text{O} = 6\text{K}_2\text{SiO}_3 + 11\text{H}_2$. The soln. do not decolorize soln. of alkali permanganates or dichromates, and it precipitates the metal from soln. of salts of copper, mercury, silver, gold, and platinum. A. Stock suggested a system of naming the silicon-oxygen compounds containing the group Si.O.Si by calling the parent hydrogen compound *siloxane*, and to specify the number of oxygen and silicon atoms by such terms as disiloxane, disilodioxane, etc.. Thus $(\text{SiCl}_3)_2\text{O}$ becomes hexachlorodisiloxane, and the term octophenyltetrasilpentoxane would be applied to:

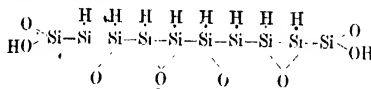

A. Stock believes it to be a mistake to apply the nomenclature of organic chemistry to the above compounds because the radicle ---SiO.OH in no way resembles a carboxy-group ---CO.OH , and he suggested using the term hydroxyoxo-group.

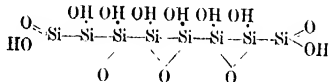

R. Formals, and A. Kolb described a silicone which they obtained by the action of boiling conc. hydrochloric acid on calcium silicide, Ca_3Si_2 . The product washed with water, and dried by treatment with alcohol, and ether had the composition of **tetradecahydrodecasildecloxane**, $\text{H}_{14}\text{Si}_{10}\text{O}_4$, or graphically:

and when dried at 120° in a stream of carbon dioxide, furnished **decahydrodecasildecloxane**, $\text{H}_{10}\text{Si}_{10}\text{O}_4$ or $\text{H}_{11}\text{Si}_{10}\text{O}_4$, or graphically:

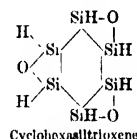

The orange-yellow crystalline mass was insoluble in water, and was bleached white on exposure to light. It is fairly stable in the presence of acids, but not so in the presence of alkalis. By employing the calcium silicide, Ca_3Si_2 , in place of Ca_2Si , A. Kolb, and R. Formals obtained a silicone with the composition of **octohydrodecosiltri-decoxane**, $\text{H}_8\text{Si}_{10}\text{O}_{13}$, or $\text{H}_7\text{Si}_{10}\text{O}_{13}$, or constitutionally:

Similarly, by treating the compound $\text{Ca}_{11}\text{N}_{10}\text{Si}_{10}$ with hydrochloric acid, they obtained a yellowish-green slimy silicone with the composition $\text{H}_4\text{Si}_{10}\text{O}_{13}$, **hexahydrodecosiltri-decoxane**. The evidence for the inclusion of these products in the list of chemical individuals is not convincing.

K. Kautsky² has studied the reaction between cold hydrochloric acid and calcium silicide, and obtained two compounds of different stages of oxidation. By treating this silicide with cold dil. alcoholic hydrochloric acid in the dark, a white, solid substance was obtained, its formation being accompanied by the evolution of hydrogen. It is spontaneously inflammable in air. Its composition corresponds with $\text{Si}_2\text{H}_2\text{O}$, and its properties indicate the constitution $\text{Si}_2\text{H.OH}$. It has been called *oxydisilene*: $\text{CaSi}_2 + 2\text{HCl} + \text{H}_2\text{O} = \text{H.Si}_2\text{OH} + \text{CaCl}_2 + \text{H}_2$. It

is a powerful reducing agent, and can be oxidized quantitatively by means of bromine to **silical bromide**, Si_2OHBr , the term **silical** being used to signify the radicle $\text{Si}_2\text{OH}-$. The reaction is symbolized: $\text{H.Si}_2\text{OH} + \text{Br}_2 = \text{Br.Si}_2\text{OH} + \text{HBr}$. Silical bromide is hydrolyzed by water to form **silical hydroxide**, a red compound, which combines with strong acids, such as hydrochloric acid, to form **silical chloride**, Si_2OHCl ; with sulphuric acid, to form **silical sulphate**, $(\text{Si}_2\text{OH})_2\text{SO}_4$; with formic acid, to form **silical formate**; or with acetic acid, to form **silical acetate**. The salts are all yellow to red in colour. The silical compounds are all powerful reducing agents. They, as well as oxydisilane, are decomposed by alkalis with evolution of hydrogen and formation of silica. F. Wöhler's silicone is considered to be oxydisilane contaminated with silical hydroxide. Halogenated hydrocarbons such as carbon tetrachloride, chloroform, or ethyl iodide in presence of traces of water and under the influence of light oxidize oxydisilane to silical compounds. The reaction does not proceed in the dark, but is extremely sensitive to light. It is remarkable that oxydisilane and the silical compounds prepared as described above retain the external crystalline form of the calcium silicide from which they are formed, and the same crystalline form persists when oxidation is carried to the final stage, silica. That the substances have a very open structure is shown by the rapidity with which the reactions proceed in the solid state, and also by the marked absorption of basic dyes by the end-product, silica. Rapid oxidation of the silical compounds, for example, by permanganate, is accompanied by the phenomenon of chemiluminescence in a remarkable degree. H. Kautsky and co-workers prefer to call oxydisilane, $\text{H.Si}_2\text{OH}$, **siloxene**, and they represent it by $\text{Si}_2\text{O}_3\text{H}_6$ or as indicated in the appended formula which they call **cyclohexasiltrioxene** because the hydrogen atoms can be replaced step-by-step by the halogens, forming a series of halogen siloxenes: thus **siloxene moniodide**, $\text{Si}_2\text{O}_3\text{H}_5\text{I}$, by the action of methyl iodide: $\text{Si}_2\text{H}_6\text{O}_3 + \text{CH}_3\text{I} \rightarrow \text{CH}_3 + \text{Si}_2\text{O}_3\text{H}_5\text{I}$; **siloxene monobromide**, $\text{Si}_2\text{O}_3\text{H}_5\text{Br}$; **siloxene tribromide**, $\text{Si}_2\text{O}_3\text{H}_3\text{Br}_3$ i.e. silical bromide, *vide supra*; and **siloxene hexabromide**, $\text{Si}_2\text{O}_3\text{Br}_6$. Siloxene does not react with methyl or ethyl iodide in darkness, but does so rapidly on exposure to light, forming the halogen-siloxene and methane or ethane. In the presence of water or amines, hydroxy- or amino-compounds are formed. Bromobenzene, the chloroacetic acids, and other organic halides react with siloxene in a similar manner. H. Kautsky and H. Zocher have investigated the chemiluminescence and photoluminescence of these compounds in some detail; their unsaturated character cannot yet be satisfactorily explained. The silical compounds may be of the oxonium salt type, and a certain similarity of some compounds of bivalent germanium suggests that the silicon in these compounds may be bivalent. Silicalammino-compounds are formed by the action of anhydrous ammonia on the silical compounds, and from these, by the action of alcohols, liquid and solid organo-silicon compounds are formed. These compounds belong to a higher stage of oxidation than the silical compounds.

The grey mass obtained by heating silicone in vacuo was considered by F. Wöhler³ to be a mixture of silicic acid and amorphous silicon. Like silicon, it dissolves slowly in alkali-lye with the evolution of hydrogen, but unlike amorphous silicon, it is completely soluble in hydrofluoric acid. O. Höhnigschmid believes that the product is a **silicon suboxide** with the formula Si_3O_2 , **silicon dinitritoxide**, but he says that he is unable to give an *unwiderleglicher Beweis* of the individuality of the assumed analogue of O. Diels' carbon suboxide C_3O_2 (q.v.). The suboxide reacts with chlorine or hydrogen chloride at a red heat, and much silicon tetrachloride is evolved; white silica remains.

A. Stock and co-workers⁴ have prepared a number of siloxanes. They found that when monobromosilane, SiH_3Br , is shaken with water, it changes into **disiloxane**, $(\text{SiH}_3)_2\text{O}$, a colourless, odourless gas, which does not ignite spontaneously but burns with a brilliant light giving a white smoke and a brown

deposit of silicon. The gas can be liquefied and solidified. The m.p. is -144° ; the b.p. -15.2° ; the sp. gr. of the liquid at -80° is 0.881; the mol. latent heat of vaporization is 5.63 Cals. The m.p. and b.p. are lower than these constants for the parent hydride, Si_2H_6 , which is the reverse of the relationships between ethane and dimethyl ether. Disiloxane is not sensibly affected when heated to 300° , but at 400° the greater portion of the substance remains unchanged, while a little hydrogen, silane, and polymeric protosiloxane is formed. It decomposes rapidly under the influence of heat when raised to redness. Submitted to a discharge of electric sparks, it slowly yields pure hydrogen. When mixed with oxygen, it inflames or explodes at once, the alteration in volume being in accordance with the equation $(\text{SiH}_3)_2\text{O} + 3\text{O}_2 = 2\text{SiO}_2 + 3\text{H}_2\text{O}$. It is not appreciably soluble in water, but soon decomposes into hydrogen and insoluble products, like $(\text{SiH}_2\text{O})_2$, etc. With sodium hydroxide, however, decomposition is complete, according to the equation $(\text{SiH}_3)_2\text{O} + \text{H}_2\text{O} + 4\text{NaOH} = 2\text{Na}_2\text{SiO}_3 + 6\text{H}_2$, which may be applied in the analysis of the gas. Disiloxane and chlorine react very vigorously at -125° ; the primary product, hexachlorodisiloxane, may be isolated, but most of it decomposes according to the equation $4(\text{SiCl}_3)_2\text{O} = 2\text{SiO}_2 + 6\text{SiCl}_4$, and some brown silicon is even formed as well. Hexachlorodisiloxane has a m.p. of -33° and a b.p. of 137° at 760 mm. Phosphorus pentoxide decomposes disiloxane at atm. temp. giving a little hydrogen, much silane, and polymeric protosiloxane. The initial reaction involves a slight hydrolysis: $(\text{SiH}_3)_2\text{O} + \text{H}_2\text{O} = 2\text{H}_2 + 2\text{SiH}_2\text{O}$, followed by a polymerization of the volatile protosiloxane to its non-volatile polymeride; the liberated hydrogen is largely utilized in reducing the disiloxane to silane: $(\text{SiH}_3)_2\text{O} + 2\text{H}_2 = 2\text{SiH}_4 + \text{H}_2\text{O}$. The water thus liberated hydrolyzes more disiloxane, and the change continues until it is arrested by the absorption of water by the excess of dry phosphorus pentoxide. The attempts to reduce disiloxane to disilene, Si_2H_4 , were not successful. R. Wintgen gave for the vap. press., p , of disiloxane, $\log p = 7.6864 - 1232.27T^{-1}$; and 5632 cal. for the latent heat of vaporization; 6560.8 cal. for the mol. heat of vaporization at 0° ; and 20.0 for Trouton's constant. Disiloxane is the first volatile compound of silicon, hydrogen, and oxygen to have been prepared. Many derivatives, with the same elements, are known, such as silicoformic anhydride, $(\text{O}:\text{SiH})_2\text{O}$, but these are no doubt polymerides, whereas alkyl, alkoxyl, and similar derivatives of the true monomeric type, for example, $(\text{SiR}_3)_2\text{O}$ and $[\text{Si}(\text{OR})_3]_2\text{O}$, have frequently been prepared. Apparently, the compound SiH_3OH , which would be the primary product of the action of water on SiH_3Br , is very unstable. It is noteworthy that the alkyl derivatives, SiR_3OH , also change into oxides readily, but the alkyl groups do confer a measure of stability on them, for hexaphenyldisiloxane, $[\text{Si}(\text{C}_6\text{H}_5)_3]_2\text{O}$, was found by F. S. Kipping and L. L. Lloyd to change back into $\text{Si}(\text{C}_6\text{H}_5)_3\text{OH}$ on boiling with alcoholic potassium hydroxide.

A. Stock and co-workers also found dibromosilane, SiH_2Br_2 , reacts with water to form hydrogen bromide and a volatile compound, probably **oxomono-silane**, or *protosiloxane*, SiH_2O —*vide* magnesium silicide. This compound was obtained as a gas by the action of the required amount of water vapour on dichlorosilane in a very large flask under greatly reduced press. It has an extraordinary tendency to polymerize, much more so than the analogous carbon compound, formaldehyde, in consequence of which the flask must be perfectly clean and smooth. Liquid and solid polymerides are formed immediately on condensation. The liquid polymerides are like benzene, and can be obtained conveniently as a soln. by shaking a benzene soln. of dichloromono-silane with water. These benzene soln. are fairly stable towards water, but reduce silver nitrate in the cold. They correspond roughly with $(\text{SiH}_2\text{O})_3$. This polymeride is an amorphous white solid, which is stable at 300° in vacuo, or in contact with boiling water, but inflames in air or chlorine, and reacts with sodium hydroxide, according to the equation $(\text{SiH}_2\text{O})_n + 2\text{NaOH} \rightarrow 2\text{H}_2 + \text{Na}_2\text{SiO}_3$. A. Stock and C. Somiesky found that dichlorosilane, SiH_2Cl_2 , with water also furnishes proto-

siloxane, and this immediately passes into **monoxodioxysiloxane**: $2\text{SiH}_2\text{Cl}_2 + 3\text{H}_2\text{O} = \text{H}_2 + 4\text{HCl} + \text{O.SiH.O.SiH}_2\text{OH}$, which, when treated with zinc methyl, forms dimethylsilane, $\text{SiH}_2(\text{CH}_3)_2$, with a m.p. -150° , and a b.p. -20° .

According to A. Stock and C. Somiesky, the hydrolysis of the halogenated disilanes corresponds exactly with that of the similar monosilanes. Thus monobromodisilane readily reacts with water to yield **tetrasiloxane**, $(\text{Si}_2\text{H}_5)_2\text{O}$, as a colourless liquid, which can be volatilized without decomposition, and when dissolved in benzene, instantaneously reduces a cold soln. of silver nitrate, but not one of copper sulphate. It reacts slowly but quantitatively with a soln. of sodium hydroxide in accordance with the equation: $(\text{Si}_2\text{H}_5)_2\text{O} + 8\text{NaOH} + 3\text{H}_2\text{O} = 4\text{Na}_2\text{SiO}_3 + 12\text{H}_2$. The solid products obtained by the hydrolysis of dibromodisilane and more highly halogenated derivatives closely resemble silico-oxalic acid, $(\text{HO}_2\text{Si.SiO}_2\text{H})_x$. They are slowly hydrolyzed further by water; they can be dried in a desiccator without marked decomposition; they are blackened by silver nitrate soln., owing to the separation of metallic silver; they evolve hydrogen when treated with alkali hydroxide; and finally they yield a residue of silicate, and explode feebly when heated on platinum foil, evolving gas and becoming discoloured. Evidently the Si-Si linking remains intact in them. Thus, two stages can be clearly distinguished in the action of alkali on $(\text{Si}_2\text{H}_5\text{O})_x$, namely, a violent evolution of gas with accompanying soln. of the substance, and then a much slower persistent change, which can speedily be brought to an end by warming the soln. The first phase corresponds with the hydrolytic separation of the hydrogen atoms, whilst the second is due to the gradual conversion of **sodium silico-oxalate** into sodium silicate and hydrogen.

C. F. Mabery⁶ said that when silica is reduced in the electric furnace, an amorphous greenish substance is formed, and its mode of formation, properties, and composition indicate that it is silicon monoxide, SiO , of sp. gr. 2.893 at 4° . C. Winkler could not prepare the monoxide by reducing silica with magnesium or silicon. At the temp. of the electric arc, however, C. Winkler's reaction, $\text{SiO}_2 + \text{Si} \rightarrow 2\text{SiO}$, can be realized. According to H. N. Potter, to effect a partial reduction of silica to silicon monoxide, a mixture of the former with the necessary proportion of carbon is heated electrically in a closed furnace of either the resistance or arc type, provision being made for withdrawing the carbon monoxide gas as it is formed. "This bursting out of the carbon monoxide gas from the point of reaction carries the silicon monoxide with it, but whether in a solid, liquid, or gaseous state is not known"; in any case, a large portion of it, at least, "is carried out of the region of reaction." Provision is made for trapping the silicon monoxide, as it escapes, in collection chambers. The reduction can be made with carbon: $\text{SiO}_2 + \text{C} \rightleftharpoons \text{SiO} + \text{CO}$; or silicon carbide: $\text{SiO}_2 + \text{SiC} \rightleftharpoons \text{Si} + \text{SiO} + \text{CO}$; and silicon itself can act on carbon monoxide, forming the monoxide: $\text{Si} + \text{CO} \rightleftharpoons \text{SiO} + \text{C}$, or the oxycarbide, $\text{Si} + \text{CO} \rightleftharpoons \text{SiOC}$ (q.v.). The reaction between silica and silicon is energetic at about 1800° . The proportion of silica and carbon in the mixture does not influence the composition of the final product, but the yield depends on the proportions of the initial materials. H. N. Potter argues that the so-called silicon monoxide is a chemical individual because its composition remains constant with wide variations in the proportions of raw materials employed; and the heat of oxidation of silicon monoxide is 200 to 800 cal. higher than that of an eq. mixture of silicon and silica. For commercial reasons H. N. Potter called the monoxide, *monox*: it contains small quantities of silicon carbide and metallic impurities. Monox is an opaque powder, silky to touch and of a yellowish-brown colour. Its sp. gr. is 2.24; and its apparent sp. gr. 2.04. It remains solid at 1700° . The vapour should be cooled as quickly as possible in its preparation to prevent as much as possible the dissociation: $2\text{SiO} \rightleftharpoons \text{Si} + \text{SiO}_2$. Monox is a good thermal and electrical insulator; its thermal resistance is 2500 thermal ohms. When dry and suspended in air, it has a negative electric charge, which depends on its fineness. It can adhere to non-conducting surfaces, such as fibres, and form a screen impervious to solid particles such as

produce tobacco smoke. The chemical properties of monox are often masked by a pellicle of silica which forms on its surface when exposed to air. Monox burns in oxygen. If blown through a flame it is oxidized and whitened, but it still retains its pulverulent form. It decomposes water with the evolution of hydrogen, but the reaction soon ceases because of the formation of a protective layer of silica. Monox dissolves in warm soln. of alkali hydroxides giving hydrogen and the alkali silicates. Hydrofluoric acid attacks it, leaving a residue richer in silicon; and if an oxidizing agent be added to the monox, all is dissolved excepting a small amount of silicon carbide impurity. When mixed with red lead, litharge, or a peroxide, and ignited, monox gives a violent reaction. Monox can be used alone or in combination as a pigment; or pressed into bricks with or without the addition of alumina, magnesia, etc., to form abrasion wheels.

C. Simmonds* showed that certain silicates—e.g. PbSiO_3 , PbSi_2O_5 , and $\text{Pb}_3\text{Si}_2\text{O}_7$ —are reduced respectively to PbSiO_2 , PbSi_2O_3 , and $\text{Pb}_3\text{Si}_2\text{O}_7$ when heated in hydrogen. No globules of lead were observed; no metallic lead appears when fused with alkali carbonates; boiling nitric acid extracts only a small fraction of the lead. He therefore inferred that virtually no metallic lead is formed but that the lead silicate is reduced to lead silicite. The reduction of the more basic silicates furnishes metallic lead. He also found that copper, iron, cobalt, and nickel silicates are similarly converted into silicites. It is more likely that the metallic lead is present in the alleged silicites, but in a very finely divided colloidal state analogous to the metallic gold in ruby glass. This lead is reoxidized when the silicate is fused with alkali carbonate; and protected from acid by the silica. W. Mostowitsch could find no evidence of the union of metallic lead with silica.

Silicon dioxide, usually called **silica**, SiO_2 , is produced by the complete oxidation of silicon, but the preparation of the oxide from the element would be a very roundabout and expensive process; nor would the product be very pure because of the difficulty in preparing even moderately pure silicon. Some of the natural varieties of rock crystal and quartz are of a high degree of purity, although contaminations may be derived from the pestle and mortar used in the comminution of the mineral. Some of the white sands—after digestion with hydrochloric acid, washing, drying, and calcination—have a high degree of purity. Anhydrous silica can be easily obtained as a white powder by calcining the hydrated silica or silica hydrogel which is formed in many reactions. For instance, (i) the silica can be separated from a powdered siliceous mineral by fusing it with alkali carbonate; digesting the cold cake with dil. hydrochloric acid; evaporating the soln. to dryness; extracting the residue with hot dil. hydrochloric acid, and then with water; and finally calcining the insoluble residue at a bright red-heat. J. N. von Fuchs⁷ precipitated the silica from the alkaline soln.; washed it with hydrochloric acid, then with water; and finally ignited the product. Again, (ii) silicon tetrafluoride, or silicon tetrachloride, is decomposed when treated with water and hydrated silica which is formed is washed by decantation; the washed silica is dried, and calcined at a red heat. This method was recommended by J. J. Berzelius, T. Graham, etc. (iii) One of the most convenient methods is to decompose a soln. of alkali silicate with dil. hydrochloric acid; to evaporate the mass to dryness; to wash the residue with dil. acid, and finally with water until free from chlorides. If further purification be desired, the product can be dissolved in the calculated quantity of soda-lye, and re-precipitated by acid. After thorough washing, the product can be dehydrated by calcination at a bright red heat. The washing of the gelatinous silica is sometimes effected in a dialyzer (Figs. 5--1, 13, 7—and Fig. 51). V. Kohlschütter and J. L. Tüscher⁸ obtained **colloidal silica**, dispersed in a gaseous medium, by making silicon one electrode of an arc, and oxidizing its vap. by a current of air.

§ 17. The Preparation of Silicon Dioxide—Quartz, Tridymite, and Cristobalite

At least seven different forms of crystalline silica are known, and possibly there are more. In addition, there are the amorphous and colloidal forms typified by the more or less hydrated opal. There is also fused or vitreous silica or quartz or quartz glass. The forms of crystalline silica stable or metastable at ordinary temp. are quartz, tridymite, and cristobalite. These forms occur in nature, although quartz is alone abundant. Indeed, F. W. Clarke¹ has shown that, next to the feldspars, quartz is the most abundant mineral on the earth's crust, and constitutes about 12 per cent. of the entire lithosphere—*vide* the occurrence of silicon.

The α -forms of quartz, tridymite, and cristobalite occur in nature; and a study of the equilibrium diagram, Fig. 26, shows that the two minerals last named are in a metastable condition. When quartz, mixed with a flux,² is heated over 870°, it passes into tridymite, and above 1470°, tridymite passes into cristobalite. The transformation of the one form into another is very slow, but the change can be hastened by the use of mineralizers and fluxes. Above 1470° quartz presumably passes into tridymite, and then into cristobalite. Since both changes are very slow, tridymite may appear under conditions where cristobalite might have been expected, and *vice versa*. On cooling, the cristobalite may pass slowly back to tridymite, and tridymite to quartz, but the back reaction is so slow that its speed has not been measured, and, at ordinary temp., the speed of the reaction is indefinitely slow. The occurrence of tridymite and cristobalite as natural minerals is evidence of the slowness of the transformation, for they seem to be taking an indefinitely long time to change to α -quartz. Some of the alleged syntheses of quartz crystals may really refer to crystals of tridymite or cristobalite, since no test was applied to distinguish which of the three forms of silicon dioxide was produced; and in some cases, it is even doubtful if the crystals were even those of silicon dioxide.

For example, F. Wöhler, and H. St. C. Deville³ described crystals of silica-pseudomorphs after silicon—by passing moist chlorine over silicon at a red heat; E. Frémy obtained pseudomorphs after silicon disulphide by exposing crystals of silicon disulphide to the action

of moist air or water vapour; he also made crystals of silica by passing a mixture of steam and carbon disulphide over briquettes made from lampblack and silica. A. Daubrée made crystals of silica by the action of silicon tetrafluoride or tetrachloride on water-vapour or on boryllia, limo, magnesite, or alumina at a red heat. R. S. Marsden obtained crystalline silica from a soln. in molten silver. F. W. Schweigger-Seidel, and E. Ripetti discussed the formation of quartz crystals in geodes in Carrara marble; T. Beigman reported the deposition of crystals of silica from an aq. soln. of hydrofluosilicic acid, allowed to stand for two years; and L. Gmelin reported that crystals of silica are deposited from an aq. soln. of silicic acid, allowed to stand exposed to air for eight years. In each case, without more evidence, there is an alternative assumption that a silicate was formed—maybe by the action of the silicic acid on the glass containing vessel.

Quartz has been formed in nature under the most diverse conditions having been produced by both igneous and aq. agencies. It occurs as a primary mineral, as a secondary deposition, and as a cementing substance.³ It is one of the essential constituents of granite, syenite, gneiss, and other acidic or siliceous rocks of igneous origin. This quartz is often peculiarly rich in liquid or gas inclusions. It is found in trachytes, porphyries, etc.; and is the main constituent in quartzite rocks, and sandstones. It permeates all kinds of rocks as an aq. infiltration; it is common in vein-stones of many rocks and in mineral veins; it occurs embedded in various limestones as chert, and flint. It occurs as a foreign mineral in cavities in basalt, limestones, marble, etc. It is the chief constituent of various gravels, sands.

The synthesis of quartz, tridymite, and cristobalite from molten magma.—

G. Rose⁴ fused (i) adularia with microcosmic salt, (ii) amorphous silica with borax and a little sodium carbonate, and (iii) amorphous silica with wollastonite; and in each case obtained tridymite. He also observed that by simple ignition quartz is transformed into tridymite. P. Hautefeuille obtained crystals of quartz by heating a mixture of amorphous silica and lithium or sodium tungstate (or a vanadate) for a long time to a temp. not exceeding 850°, but if the temp. be between 850° and 1000°, crystals of tridymite are formed. He also obtained quartz and felspar by heating above 700° a mixture of silicic acid, alumina, alkali phosphate, and alkali fluoride. P. Hautefeuille and J. Margottet obtained similar results by using a mixture of lithium chloride and oxide as an *agent minéralisateur*; O. Kieuffat used phosphoric acid; F. H. Clews and H. V. Thompson, sodium chloride; A. L. Day and co-workers, a mixture of potassium chloride with 20 per cent. of lithium chloride; F. Parmentier used sodium molybdate; and P. D. Quensel, tungstic oxide. The last-named said that quartz is formed below 1000° and tridymite above that temp.—J. Königsberger said 1050°, and he also found that the presence of boric oxide retards the formation of quartz crystals. N. Parravano and C. R. del Turco studied the effect of ferric, phosphoric, boric, calcium, and tungstic oxides on the conversion of quartz. S. Meunier obtained tridymite from a fused mixture of silica, potassium hydroxide, and aluminium fluoride. K. von Chroustschoff obtained tridymite by fusing rocks rich in silica; and P. D. Quensel, by fusing a mixture of oligoclase, quartz, and tungstic oxide. K. B. Schmutz melted together a mixture of granite, sodium chloride, and sodium tungstate and found crystals of plagioclase, augite, and tridymite in the cooled mass. P. Hautefeuille and A. Perrey obtained tridymite in their experiments on the synthesis of phenacite, and emeralds. K. Bauer obtained tridymite by melting mica-schists with silica, or potash mica with sodium or calcium fluoride, sodium chloride or sodium tungstate. J. Lenarcie obtained no tridymite by fusing mica-schist or gneiss with fluorides, tungstates, or molybdates, but he did obtain crystals of quartz. R. Schwarz obtained crystals of tridymite by fusing sodium silicate with three times its weight of sodium phosphate for 6 hrs. at 1000°; the soluble salts were removed by washing with water on a filter. K. Bauer obtained quartz from fused diorite; and from a mixture of diorite, orthoclase, albite, mica, or hornblende with sodium chloride, potassium tungstate, sodium phosphate, and boric oxide. G. Medanich obtained quartz with glass inclusions by cooling a molten

mixture of granite, sodium hydrophosphate, boric acid, and tin chloride. This subject was also investigated by K. Petrasch. H. E. Benrath observed quartz crystals in a devitrified potash-soda-glass, but F. Fouqué and A. M. Lévy could not confirm this; and J. Morozewicz obtained under similar conditions crystals of tridymite. The last-named said that if an aluminous silicate-magma is super-saturated with silica, the excess separates out on cooling as tridymite and a prismatic modification of crystalline silica. A liparite magma containing one per cent. of tungstic oxide furnished a mixture of quartz, sanidine, and biotite. He said that the function of the tungstic oxide is to liberate silica at a lower range of temp. within which quartz is the stable phase. It will be observed that in the experiments just cited, G. Rose, P. Hautefeuille and co-workers, S. Meunier, K. von Chroustschoff, K. Bauer, R. Schwarz, K. B. Schmutz, J. Lenarcic, G. Medanich, and A. L. Day synthesized tridymite—*vide infra*. H. le Chatelier, and G. V. Wilson observed crystals of tridymite in the devitrification of a lead-glass.

The synthesis of quartz, tridymite,* and cristobalite from solutions.—C. Schafhäutl⁵ synthesized quartz by simply heating a soln. of colloidal silica in an autoclave for 8 days. H. de Sénarmont worked in a somewhat similar way at 200°–300°, but instead of water, he used dil. hydrochloric or carbonic acid. K. von Chroustschoff obtained quartz by heating an aq. soln. of colloidal silica to 250° for several months; and with a mixed soln. of silica and hydrofluoboric acid; at 180°–228°, he obtained cristobalite; at 240°–300°, quartz was formed; and at 310°–360°, tridymite. G. A. Daubrée heated water in a glass tube to about 300°, and obtained crystals of quartz and some silicates by the action of the water on the glass. He also found that quartz crystals are formed when water from the thermal spring at Plombières is heated; and F. Fouqué and A. Michel-Lévy found that some chalcedony is formed at the same time. W. Bruhns heated to about 300° under press., a mixture of powdered glass and a dil. soln. of ammonium fluoride, and obtained quartz; when a mixture of felspar and hydrofluoric acid was similarly treated for 53 hrs., tridymite was formed. J. Königsberger and F. W. J. Müller heated glass and water over 300°, and obtained quartz, tridymite, and soda felspar; the filtered soln. slowly deposited quartz and opal; and the undissolved residue contained both tridymite and felspar. G. Maschke heated a soln. of sodium silicate in a sealed glass tube, and when the temp. was below 180°, he obtained crystals of hydrated silica, but above that temp., quartz crystals were formed. C. Friedel and E. Sarasin obtained quartz by heating nearly to redness a mixture of potassium hydroxide, gelatinous silica, and alumina for 14–38 hrs. in a steel tube. At a still higher temp., crystals of quartz and tridymite were found side by side. E. Baur heated in a steel autoclave at 250°, for 6 hrs., a soln. of silicic acid and potassium aluminate; when the proportion of SiO_2 : KAlO_2 was between 5 : 2 and 5 : 25, orthoclase, tridymite and quartz were formed, while with sodium aluminate in place of the potassium salt, crystals of albite and quartz were produced, and with SiO_2 : NaAlO_2 as 5 : 25, quartz alone was formed. G. Spezia found that the evaporation of an aq. soln. of silicic acid furnishes opal, and if alkalis are present quartz is produced; if opal be heated with a soln. of an alkali silicate, an aggregate of quartz crystals is formed. A hot dil. soln. of sodium silicate dissolves some quartz, and the latter is re-deposited at a lower temp. He found that the soln. and re-deposition of quartz is not affected by press., but is sensitive to variations of temp. A. L. Day and co-workers obtained fine crystals of quartz by heating to 400°–450° a mixture of magnesium ammonium chloride, sodium metasilicate, and water for 3 days in a steel bomb. It will be observed that in the experiments just indicated C. Friedel and E. Sarasin, K. von Chroustschoff, W. Bruhns, E. Baur, and J. Königsberger and F. W. J. Müller obtained tridymite, and that K. von Chroustschoff also obtained cristobalite.

The mutual conversion of the different forms of silica.—H. Rose⁶ pointed out that before the discovery of tridymite in nature by G. vom Rath, it had been

actually prepared by G. Rose—*vide supra*. H. le Chatelier observed tridymite was formed by the prolonged heating of quartz in a steel furnace. E. Mallard also observed the development of tridymite, in silica bricks, made from quartz sand mixed with about 2 per cent. of lime, which had been heated for 18 months in a steel furnace at Assialy. W. Sokoloff said that in the transformation the flux seemed to dissolve the quartz and reject it as tridymite. Similar changes have been noted in silica bricks by W. Sokoloff, P. J. Holmquist, K. Endell, A. Scott, etc. C. F. Rammelsberg noted that the calcination of amorphous silica changes it into tridymite. L. Elsner said that rock-crystal is not changed when heated for some days in a porcelain oven (1400° – 1600°), but E. Cramer, K. Endell, H. and G. Rose, etc., have noted that under these conditions quartz is changed into tridymite, or a form with a low sp. gr. H. Schulze and A. Stelzner noted the formation of tridymite in the walls of a zinc retort; and A. Lacroix in the bricks of a glass furnace at Clichy. A. Schwantke observed tridymite in roofing slates which had been struck by lightning. C. Vélain found crystals of tridymite, anorthite, and wollastonite in the glass formed by the ashes of wheat and oats during the conflagration of grain mills at Petit-Brie and at Nogentel. E. Mallard also noted that fibrous tridymite had accumulated in a cavity in the masonry of a steel furnace; the fibrous silica observed by L. N. Vauquelin in the bottom of an iron smelting furnace was probably tridymite. This form of silica occurs in white silky fibres resembling asbestos and has hence been called *Eiscnamianth*—possibly some graphite and titanium cyanide and nitride are also present. C. Schnabel, C. W. C. Fuchs, P. C. Grignon, and F. C. L. Koch also discussed the occurrence of fibrous silica in the masonry of furnaces. According to A. C. Hawkins, a fibrous quartz resembling asbestos occurs in the metamorphic slates at several localities on Rhode Island. A. Brun transformed quartz-glass into crystallized quartz by heating it between 700° – 750° in the vapours of alkali chlorides; between 800° and 1000° , tridymite was formed. C. Johns found that quartz-sand was transformed to tridymite at 1500° , and suggested that the inversion temp. was 200° lower. E. Sommerfeldt, and A. Blackie noted the transformation of quartz-glass into tridymite at 1200° – 1300° ; and M. Herschkowitsch noted the formation of crystals of quartz when quartz-glass is heated over the gas blowpipe flame. A. L. Day and E. S. Shepherd found that quartz and amorphous silica are transformed into tridymite at about 1000° , and in the presence of alkali chlorides the transformation occurs at about 800° , and in the back-reaction occurs at about 750° . For C. N. Fenner's observations, *vide infra*.

Owing to the very small differences in the properties of tridymite and cristobalite, it is more than likely that many of the alleged transformations of silica and quartz into tridymite were really transformations into cristobalite. C. N. Fenner has shown that tridymite is transformed into cristobalite above 1470° . P. J. Holmquist, K. Endell, A. Lacroix, A. Scott, etc., have studied the conversion of quartz or tridymite into cristobalite, and also the formation of cristobalite in silica bricks in high temp. furnaces. F. E. Wright, E. S. Shepherd, and G. A. Rankin found that cristobalite is formed during the slow cooling of molten quartz glass, and C. N. Fenner observed that if a mixture of tridymite and sodium tungstate be heated for 10 hrs. at 1475° , a considerable proportion is transformed into cristobalite, but below that temp. no cristobalite is formed.

There are abrupt changes in the properties of quartz at about 575° , and hence quartz below this temp. is designated α -quartz and above this temp. β -quartz. The change is reversible. There are also reversible changes in the properties of tridymite at about 117° , and in those of cristobalite at about 270° . H. Steinmetz found the transition point of tridymite to be 115° , and the change is attended by a 0.6 per cent. expansion. The lower temp. forms are called respectively α -tridymite and α -cristobalite; while the higher temp. forms are called respectively β_1 - and β_2 -tridymite and β -cristobalite. With β_1 -tridymite there is another change at about 163° , and above that temp. β_2 -tridymite is formed. The complex series of

changes which occur during the calcination of quartz, tridymite, and cristobalite have been elucidated by the work of C. N. Fenner, K. Endell, W. P. White, J. A. Cunningham, J. Königsberger, A. Scott, P. Braesco, J. B. Ferguson and H. E. Merwin, H. le Chatelier, etc.

The effect of raising the temp. of quartz, tridymite, cristobalite, and vitreous quartz is summarized in Fig. 26, after C. N. Fenner. With quartz, at about 575°, α -quartz changes into β -quartz, and at the same time there is a slight decrease in density. The reverse transformation occurred at 570°. Another change takes place at 870° \pm 10°, for β -quartz then changes into what is called β_2 -tridymite; at 1470° \pm 10°, β_2 -tridymite changes into β -cristobalite, which melts at 1625°.

To summarize, the region of stability of each form lies between the transition points :

If α -tridymite be heated on a gradually rising temp., it changes at about 117° into β_1 -tridymite, and at 163°, β_1 -tridymite changes into what is called β_2 -tridymite, which then changes on subsequent heating at 1470° into β -cristobalite, which melts at 1625°. The transition points of α - into β_1 -, and of β_1 - into β_2 -tridymite are shown on the curves, Fig. 26, where the press. are diagrammatic. The β_1 to β_2 -tridymite transformation is supposed to be analogous with the α - to β -quartz transformation. To summarize, the region of stability of each form lies between the transition points :

According to H. le Chatelier, cristobalite is the metastable phase in relation to tridymite, so that above 1480°, tridymite is more stable than cristobalite; while, according to A. Scott, tridymite is the stable phase up to at least 1550°, since bricks containing 97 per cent. of silica are practically all tridymite after being at this temp. for prolonged periods. C. N. Fenner, however, claimed that in the absence of an *agent minéralisateur* the transformations between tridymite, cristobalite, and quartz are remarkably sluggish, and that because tridymite can be heated in a dry state at temp. exceeding 1480° without transformation is of no importance in drawing conclusions as to stability relations, when under proper conditions it can be converted into cristobalite; and he has again emphasized that at temp. above 1470° \pm 10°, quartz, tridymite, and amorphous silica have repeatedly and unequivocally been converted into cristobalite; between 1470° \pm 10° and 870° \pm 10°, quartz, cristobalite, and amorphous silica have similarly been converted into tridymite; and below 870° \pm 10°, tridymite, cristobalite, and amorphous silica have been converted into quartz. J. B. Ferguson and H. E. Merwin also demonstrated that the stability region for cristobalite lies above that for tridymite.

Similarly, if α -cristobalite be heated, it passes into β -cristobalite at about 225°, and this melts at 1625°. The transition temp. 225° is not sharply defined, since in the conversion of α - to β -cristobalite, the observed values ranged between 274.7° and 276.9°; and for the reverse transformation, between 240.5° and 198.1°. To summarize, the region of stability of each form of cristobalite lies between the transition points :

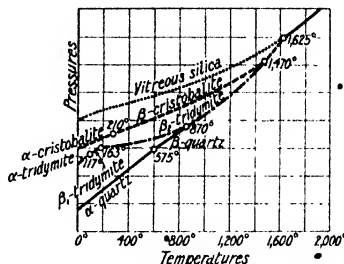

FIG. 26.—The Equilibrium Conditions of Quartz, Tridymite, and Cristobalite.

The relationship between these different forms of silica is illustrated diagrammatically in Fig. 26. So far as information is at present available, the more important physical properties of the products of these different mutations of quartz and its polymers are summarized in Table II.

TABLE II.—PHYSICAL PROPERTIES OF THE DIFFERENT MODIFICATIONS OF SILICA

	Crystal system.	Specific gravity.	Index of refraction (sodium light).	Double refraction.	Polarization (sodium light).
α -Quartz	Hexagonal	2.65	n_ω , 1.5352 (570°) n_ϵ , 1.5328 (570°)	+0.0091 (20°) +0.0080 (570°)	21.7° (20°) 24.1° (560°)
β -Quartz	Hexagonal	2.633	n_ω , 1.5328 (580°) n_ϵ , 1.5404 (580°)	+0.076 (590°) —	2.52° (600°) —
α -Tridymite	Rhombic(?)	2.28	1.4775	+0.0021	—
β -Tridymite	Hexagonal	2.30	—	Feeble	—
β -Tridymite	Hexagonal	—	—	—	—
α -Cristobalite	Tetragonal	2.348	1.486	-0.00053 (?)	—
β -Cristobalite	Cubic	2.215	—	Feeble	—
Silica glass	Amorphous	2.21	1.460	Nil.	Nil.

The form of quartz present in chalcedony shows no signs of the transformation at 575°, and, when fused with sodium tungstate, seems to change directly into β -tridymite at about 870° without showing the 575° transition point. This is possibly an effect of the greater speed at which chalcedony passes into the form with a low sp. gr. C. N. Fenner, however, suggests that the quartz of chalcedony may be another modification of silica different from quartz. A. Wietzel concluded from his observations on the sp. ht., etc., that chalcedony is not a distinct form of silica, but simply microcrystalline quartz; he also studied the stability of the different forms of silica when associated with quartz-glass.

J. Morozowicz⁷ reported a prismatic modification of quartz to be formed along with tridymite when an aluminous magma supersaturated with silica is allowed to cool; and F. Fouqué and A. M. Lóvy also said that a prismatic form of silica is produced when an excess of silica is fused with augite, enstatite, or hypersthene.

The different varieties of natural quartz have different speeds of conversion.⁸ J. W. Mellor and A. J. Campbell found that quartz was transformed much more slowly than flint. If S denotes the sp. gr. of the material after n firings in a pottery oven, they found that with flint, $S(6.7 - e^{-1.05n}) = 14.87$; and with quartz, $S(7.8 - e^{-0.31n}) = 18.096$. J. T. Robson also found that flint and chalcedony changed more quickly than sand and quartz rock. The subject was studied by A. Grün.

Analyses of quartz, tridymite, and cristobalite.—J. G. Wallerius⁹ did not give an analysis of quartz or *Kiesel* in his description of this mineral in 1750. In 1779, T. Bergman gave for the analysis of a specimen of rock-crystal: Silica, 93 per cent.; alumina, 6 per cent.; and calcium oxide, 1 per cent. M. H. Klaproth, D. L. G. Karsten, and C. F. Bucholz also made analyses of varieties of quartz. Good rock crystal contains 99.5 per cent. of silica. Numerous analyses—F. A. Genth, P. Schweitzer, J. W. Mallet, A. des Cloizeaux, C. F. Rammelsberg, P. Holland, A. Becker, etc.—have been made. Analyses of tridymite have been made by G. vom Rath,¹⁰ N. S. Maskelyne, V. Wartha, A. Koch, C. Winkler, etc. G. vom Rath analyzed cristobalite—*vide supra*.

E. Weinschenk¹¹ found traces of titanium, iron, and manganese in many varieties of quartz; and manganese was also found in a blue quartz. A. Nabl found iron, sulphur, and nitrogen in amethyst. L. Wöhler and K. von Kraatz-Koschlau found no sulphur. A. Nabl found ferric oxide in citrine quartz. C. F. Rammelsberg said amethyst from Brazil contains 0.01 per cent. manganese,

and a clear quartz had 0.02 per cent. ferric oxide, 0.02 per cent. calcium oxide, and 0.04 per cent. soda; an amethyst had 0.0027 per cent. of carbon. S. Curie and S. E. Gleditsch found traces of lithium in transparent quartz. N. von Fuchs found 1.0 to 1.5 per cent. titanio oxide in rose quartz. A. Forster obtained 0.5 to 0.6 grm. of ammonium carbonate by distilling 4.5 kgrms. of smoky quartz. E. Wülfing found no perceptible loss of weight when smoky quartz is decolorized at 300°—*vide* the occurrence of coloured quartz.

Quartz crystals may show cavities containing liquid, solid, and gaseous inclusions—*vide* 1. 11, 2, Fig. 3. H. Davy¹² found that the cavities in rock crystal contained water with a trace of alkali sulphates, and nitrogen gas. D. Brewster found that the fluid enclosure contained crystals of calcium carbonate. F. Salm-Horstmar found traces of chlorine in quartz, and he assumed this was derived from alkali chlorides present as impurities. H. C. Sorby found cubic crystals contained in the liquid in the cavities of some quartz crystals, and he believed these crystals were sodium chloride. This was confirmed by the observations of F. Zirkel, H. Rosenbusch, E. Warburg and F. Tegetmeier, J. Königsberger, etc. J. Königsberger and W. J. Müller analyzed the inclusion in the cavity of a sample of quartz from Bächistock (Switzerland) and found:

	H ₂ O	CO ₂	CO ₂	SO ₂	Cl	Na	K	Li	Ca
Per cent.	83.4	9.5	1.8	0.5	1.6	2.0	0.7	0.2	0.3

H. C. Sorby found alkali and calcium sulphates, free acid, and in some cases almost pure water. H. Vogelsang found spectroscopically cavities with an aq. soln. of carbon dioxide, and also with liquid carbon dioxide—the liquid disappears when the temp. is raised above the critical point, 32°. This agrees with the observations of D. Brewster, T. Simmler, W. E. Hidden, J. Bosscha, H. Geissler and H. Vogelsang, etc. C. W. Hawes found so much carbon dioxide under press. in the cavities in a quartz from Brancheville (Conn.), that when broken up with a hammer, some of the cavities burst open with a report; A. W. Wright obtained from this same quartz a gas with 98.32 per cent. carbon dioxide, and 1.68 per cent. nitrogen along with smaller amounts of sulphur dioxide, hydrogen sulphide, volatile hydrocarbons, ammonia, and chlorine; or if referred to the accompanying water, 30.48 per cent. carbon dioxide, 0.50 per cent. nitrogen, and 69.02 per cent. water. From the basis of the ratio of liquid to gaseous carbon dioxide in the inclusions, and other known data, A. Johnsen, and O. Mügge endeavoured to calculate the conditions under which particular specimens have been formed. The quartz is used as a kind of geological thermometer. C. L. Reese, and G. Tschermak reported that petroleum enclosed in the cavities of some crystals from Guntersville (Alabama), and asphaltum in crystals from Herkimer Co. (New York). H. Sjögren found methyl disulphide or ethyl hydrosulphide in quartz from Salangen. J. G. Bornemann found plant remains in the rock crystal from Oberlungwitz and Radowenz in Bohemia. G. Tschermak gave the following list of minerals he had observed included in quartz:

Magnetic pyrites, mispickel, pyrite, argentite, antimonite, molybdenite, zinc blende, anatase, rutile, hematite, ilmenite, magnetite, dolomite, calcspar, amphibole, topaz, feldspar, tourmaline, muscovite, chlorite, epidote, titanite, laumontite, desmine, and pilnrite. G. A. Kenngott, and R. J. G. Beaugoy observed anhydrite included in quartz.

§ 18. The Physical Properties of Silicon Dioxide

The colour of quartz has been indicated in connection with the occurrence of this mineral. O. Ruff and P. Schmidt said the vapour at 1900°–2160° is blue. The crystalline form of quartz attracted the attention of Pliny, who, in his *Historia naturalis* (6, 37, c. 77), said that "it is not easy to account for the regular hexagonal shape and smoothness of the crystals and this the more as the pyramidal terminations do not always have the same appearance." Quartz crystals furnished N. Steno (1669)² with material for his work on the constancy of the angles of crystals. M. A. Cappeller made a measurement of the angles of the crystals in 1723. In 1783, J. B. L. Romé de l'Isle measured the angles of several varieties of quartz, and showed that *il n'y a qu'une seule espèce de cristal de roche; that les masses moins régulières ou moins homogènes prennent les noms de quartz, de grès, d'agate, caillou, jaspe, etc.*; and that amethyst is nothing but rock crystal coloured violet or purple. Observations were also made by R. J. Haüy, C. S. Weiss, H. Dauber, G. Rose, N. von Kokscharoff, W. Haidinger, J. Bindrich, S. Ichikawa, M. Websky, A. des Cloizeaux, G. Sella, F. Hessenburg, F. Leydolt, V. von Lang, etc. The typical quartz crystal is a doubly terminated hexagonal prism (Fig. 27), and it appears as if it were a combination of a hexagonal prism and a bipyramid. Some

typical crystals remaining after the dissolution of the calcium carbonate from some Derbyshire limestones are illustrated by the photograph, Fig. 27. Confer Fig. 70,

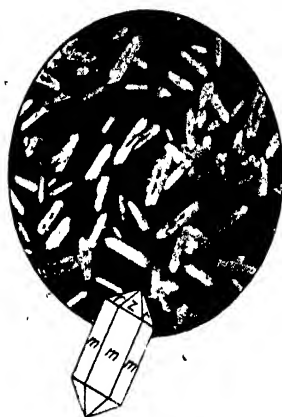

FIG. 27.—Quartz Crystals.

1, 11, 7, in some cases the crystals appear as the simple bipyramids. Quartz crystals belong to the hexagonal system. According to A. T. Kupffer, the axial ratios are $a : c = 1 : 1.09997$, and the constants of the forms: $r \{100\}$, $z \{22\bar{1}\}$, $m \{2\bar{1}\bar{1}\}$, are mr , $38^\circ 31'$, and rz , $46^\circ 31'$. A. N. Winchell found a rock from a mine near the Iron River, Michigan, contained isotropic quartz. The quartz gave the standard X-radiogram so that the apparent isotropism was attributed to the extremely fine state of subdivision of the mineral.

The trigonal symmetry of quartz is illustrated by crystals with three alternate faces of the pyramid larger than the remaining three, showing that the hexagonal bipyramid consists of two rhombohedra; by crystals which are terminated by one rhombohedron, and by crystals which occur as simple rhombohedra. Crystals with certain faces only on alternate corners show that

the crystals are trigonal trapezohedra. These crystals possess no centre or plane of symmetry, and they are enantiomorphous, Fig. 27. The two sets of faces may form what are conventionally known as right- and left-handed quartz crystals: a crystal of the one kind is a mirror image of the other. The two kinds are about equally numerous. When complementary right- and left-handed faces occur on the same crystal, it is not a single crystal but an interpenetrant twin. Two right-handed or two left-handed, or a right- and left-handed, crystals may be twinned by interpenetration parallel or perpendicular to the prism edge. The twinning of right- and left-handed crystals frequently occurs in quartz crystals from Brazil, and is hence called *Brazilian twinning*; Fig. 30 is an example; and the twinning of two right- or two left-handed

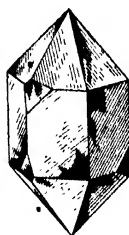

FIG. 28.—Left-handed Quartz.

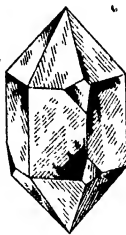

FIG. 29.—Right-handed Quartz.

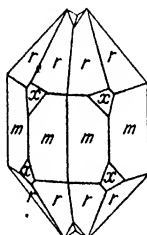

FIG. 30.—Brazilian Twinning.

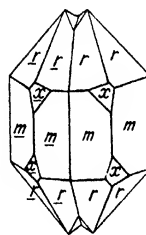

FIG. 31.—Dauphiné Twinning.

crystals is called *Dauphiné twinning*—after Dauphiné, near Bourg d'Oisano. There is also twinning by juxtaposition, forming genicular (Fig. 32), three-rayed, and cruciform (Fig. 33) twins. G. Friedel, and J. Beckenkamp have discussed the twinning laws of quartz. Mis-shapen and distorted crystals with horizontal striations are also found. O. Mügge showed that while α -quartz crystallizes in the trapezohedral-tetartohedral division of the hexagonal system, β -quartz is also hexagonal but has

trapezohedral-hemihedral symmetry. The axial ratios of the two forms are nearly identical. The only crystallographic change which occurs during the passage from α - to β -quartz is a molecular rearrangement, so that the common digonal axes of the β -form become polar in the α -form.

Quartz which has been formed above 575° can be distinguished from quartz which has never reached that temp. At ordinary temp. all quartz is α -quartz, but if at any time in its history a particular piece of quartz has passed the inversion point and been heated above 575° , it bears ever afterwards marks potentially present which on proper treatment can be made to appear just as an exposed photographic plate can be distinguished at once from an unexposed plate on immersion in a proper developer, although before development both plates may be identical in appearance.

FIG. 32.—
Genicular
Twin.

FIG. 33.—
Cruciform
Twin.

F. E. Wright and E. S. Larsen go further and say that quartz can be used as a geological thermometer, because, if at any time quartz has been heated above 575° , this fact is recorded in its structure by the corrosion figures. Hence also, quartz in any rock must have been formed below 870° , and its peculiarities indicate whether it was crystallized below or above 575° .

During the microscopic examination of some pieces of trachytic porphyry from San Cristobal, near Pachuca (Mexico), in 1863, G. vom Rath³ found some hexagonal tabular crystals of *eine neue Krystallform der Kieselsäure* which frequently exhibited compound twinning, and since there were usually three individuals in one compound form, he named the crystals tridymite—from *τρίδυμος*, triplet. The crystals had a sp. gr. varying from 2.295–2.326 (15° – 16°), thus corresponding with opal rather than with quartz; and they furnished on analysis: 96.1 per cent. of silica; 1.9, ferric oxide; 1.3, alumina; and 0.66, loss on ignition. G. Rose then showed that if powdered rock crystal or amorphous silica be calcined in a porcelain oven, or if adularia or amorphous silica be heated with microcosmic salt, tridymite is usually obtained. The crystals, Fig. 34, are thin hexagonal plates bounded by the faces c (0001), m ($10\bar{1}0$), and the subordinate faces a ($11\bar{2}0$), and p ($10\bar{1}1$). The crystals may show juxtaposition twins, or trillings; or the twins may be formed by interpenetration, and they may occur in fan-shaped groups, or spherical aggregates. According to R. Brauns, and E. Mallard, the crystals of silica from the Euganean Hills, which A. Lasaulx described as tridymite, are really quartz crystals into which the original tridymite has changed. He found that crystals of tridymite from Cerro San Cristobal, and Mont Doré, are pseudo-hexagonal, but they belong to the rhombic system and have the axial ratios $a : b : c = 0.5774 : 1 : 0.9405$. There is a change of tridymite into a hexagonal form near 130° , so that silica can exist in two crystalline forms of hexagonal symmetry; one of the forms is quartz, the other tridymite. The axial ratio of β_1 -tridymite at 130° is $a : c = 1 : 1.65304$. F. Wallerant regarded tridymite as a monoclinic mineral with rhombic symmetry. The crystals have also been studied by A. Merian, G. Boeris, R. Panebianco, M. Schuster, J. Beckenkamp, E. Billows, F. Sandberger, and F. Zirkel. Tridymite is found in certain acidic volcanic rocks; the primitive rocks on the earth's crust, however, always have their free silica in the form of quartz. N. S. Maskelyne described crystals of a variety of silica which he found in a meteorite from Breitenbach (Bohemia), and which he named *asmanite*—from the Indian term *a-smān*, thunderbolt. M. Schultze showed that asmanite and tridymite are the same mineral species. E. Mallard showed that *lussatite* is a fibrous scaly aggregate of crystals with a weaker double-refraction than that of quartz; and F. Slavik said that lussatite is probably a fibrous variety of tridymite mixed with a little opal.

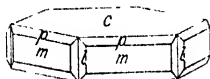

FIG. 34.—Idealized Crystal
of Tridymite.

In 1887, G. vom Rath also found as an inclusion in the augite of San Cristobal

another form of crystal different from tridymite and quartz; the analysis was: SiO_2 , 91.0 per cent.; Fe_2O_3 and Al_2O_3 , 6.2 per cent. He named the crystals cristobalite from the place where they were found. The external form of the crystals can be referred to the regular octahedron. According to E. Mallard, cristobalite is a distinct species and not a mere variety of tridymite, although the sp. gr. are so nearly alike. The crystals which are usually imperfect are pseudo-cubic, but they really belong to the tetragonal system; they are grouped in such a way that the bases of six pyramids represent the six faces of a cube. There is a similar grouping in analcime, and E. Mallard added, that, like analcime, cristobalite is only approximately tetragonal and uniaxial, and ought rather to be regarded as rhombic. At 175° , he says, cristobalite undergoes a reversible change, all birefracton disappears, and the crystals acquire the optical properties proper to their external cubic form. Hence, α -cristobalite is regarded as tetragonal, and mimetic cubic; while β -cristobalite is cubic. J. Beckenkamp, O. Mügge, and P. Gaubert have made observations on this subject.

The crystalline form of chalcedony has not been determined, although C. Hintze⁴ said that it is *vielleicht rhombisch*. Chalcedony and flint are usually said to be cryptocrystalline. Chalcedony occurs in mammillary, botryoidal, or stalactitic masses, and lining or filling cavities in rocks. Opal and vitreous silica are amorphous. According to F. Savart, quartz does not admit of cleavage in the ordinary way, but if the prism be made red hot and suddenly cooled, the fractures which occur give rhombohedral pieces. Hence he infers that the primitive form is the rhombohedron like that which would be obtained if the crystal were susceptible of cleavage parallel to the three non-adjacent faces of the prism. E. W. Washburn and L. Navias conclude from their examination of the X-radiograms of quartz, tridymite, cristobalite, silica glass, raw and calcined flint and chalcedony, that calcined chalcedony can be regarded as a kind of silica glass; while calcined flint may be either cristobalite or tridymite. Raw flint and raw chalcedony contain much quartz in a colloidal state. R. Wietzel⁵ found chalcedony to be simply microcrystalline quartz.

Lord Kelvin, S. Nakamura, and S. Ichikawa studied the molecular structure of quartz. The X-radiogram of quartz has been investigated by W. H. Bragg. He refers the lattice to a set of hexagonal axes, because this gives the simplest explanation of the observed spectra. The value of a is 4.89×10^{-8} cm., and there are three mols. of silica, SiO_2 , associated with each point of the lattice as structural units or crystal mols. The quartz lattice is produced by three interpenetrating hexagonal lattices. These are so related that they can be derived from each other by a rotation of about $\frac{2}{3}\pi$, and a translation of $\frac{1}{3}c$ along an axis parallel to the direction of c , Fig. 35, where $a : c = 1 : 1.10$. Each hexagonal lattice locates the position of one-third the triplets. Each trigonal axis of the structure has points arranged spirally about it; and, since a spiral can be either left- or right-handed, the enantiomorphism of quartz follows.

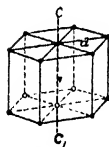

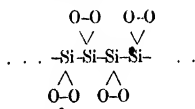

FIG. 35.—Cell of Space Lattice (W. H. Bragg).

J. Beckenkamp assumed that the silicon atoms form a rhombohedral lattice instead of a three-point screw as in W. H. Bragg's structure. J. Beckenkamp's lattice of ordinary quartz is in effect a 3-fold triangular prismatic lattice with the trigonal axis vertical, Fig. 36. The solid circles represent one layer of silicon atoms, the second circles another layer, and the open circles a third layer. The fourth layer is like the first, the fifth like the second, etc. The positions of the oxygen atoms represented by small circles in the diagram depend on whether the crystal is right- or left-handed. In right-handed quartz, the oxygen atoms are situated as in the inset of Fig. 36, where the lowest layer of atoms is numbered 1, the next layer 2, the next 3, . . . The pairs of oxygen atoms 1 and 3, 4 and 6, 7 and 9, are associated respectively with the silicon atoms 2, 5, and 8. The series of 9 atoms of three SiO_2 -triplets thus form a helix rotating to the right. The spiral structure appears only after the introduction of the oxygen atoms, the arrangement of the oxygen atoms is such that the orienta-

tion of the valency directions is the same in horizontal or vertical mol. layers, and the optical rotation perpendicular to the vertical axis is then explained. S. Kyropoulos, C. Mauguin, L. W. McKeehan, E. W. Washburn and L. Navias, H. Haga and F. M. Jäger, and F. Rinne have discussed the X-radiogram of α -quartz; S. Kyropoulos found quartz-glass and silicic acid are amorphous. M. L. Huggins, L. W. McKeehan, and R. B. Sosman have suggested a possible structure for the quartz mols.

According to the theory of the electric structure of atoms (4, 27, 3 and 4), the silicon atom has a nucleus with a positive charge of 14, and surrounded by 14 non-nuclear electrons; the oxygen atom likewise has a nucleus with a positive charge of 8, and surrounded by 8 non-nuclear electrons. Each atom of both elements has an inner ring of two electrons, and outside the inner ring there is a ring of 6 electrons with the oxygen atom; and with the silicon atom two rings with 8 electrons in the inner ring and 4 in the external ring. Both silicon and oxygen have a tendency to complete a stable external ring of 8 electrons. This tendency causes the combination of silicon and oxygen to form three interlocking systems corresponding with the single mol. of silica, SiO_2 , Fig. 37. Three such mols. would form a structural triplet unit. The resulting 3-atom mol. is roughly tetrahedral because of the grouping of the electrons of the octet in pairs, and the three are closely assembled with an atom triplet which is approximately trigonal. R. B. Sosman tried to follow in imagination the changes which occur as quartz glass crystallizes; and as the different forms of silica pass through their different inversion points. It is assumed that the atom-triplet SiO_2 maintains its individuality in all forms of quartz and silicates (*q.v.*). The union of these triplets furnishes a silica-thread:

These threads are supposed to form in the liquid state or even in the vaporous state. In the liquid they are in a constant state of vibration and movement, with the oxygen atoms in haphazard orientation relative to the thread. On this view, solid silica glass is analogous to a compressed pad of wires. The thread structure is believed to persist in the crystalline state, and the three principal crystalline modifications (cristobalite, tridymite, and quartz) are built up by combining the threads through the oxygen atoms. The high to low inversions (α - β) in all three forms are considered to be due to a change in the state of motion of certain electron orbits resulting from increased thermal vibration of the atoms. These changes produce sudden alterations in the shape of the silica triplet and the relative positions of the two oxygen atoms. In cristobalite, the oxygen atoms of the silica threads are incompletely fixed, some of the threads being capable of rotation about the silica axis. This explains the variable inversion point of this form of silica. F. Rinne, and J. Beckenkamp have made suggestions about the structure of β -quartz; and J. Beckenkamp, about the structures of tridymite and cristobalite.

The natural and artificial etching of quartz crystals brings out the peculiarities

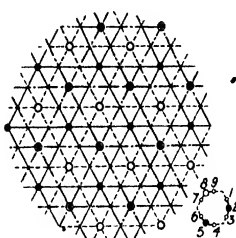

FIG. 36.—Rhombohedral Lattice of Silicon Atoms in Ordinary Quartz; and, in inset, Arrangements of Atoms in Right-handed Quartz.

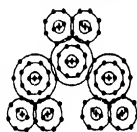

FIG. 37.—Electronic Structure of the Silica Molecule.

of twinning, and the enantiomorphism of the crystals. The corrosion figures of left-handed quartz are complete mirror images of those of right-handed quartz, as illustrated by Fig. 40. The etching of quartz with *hydrofluoric acid* has been

FIG. 38.—Arrangements of Atoms in Right-handed Quartz Crystal.

FIG. 39.—Arrangements of Atoms in the Brazilian Twinning of Quartz.

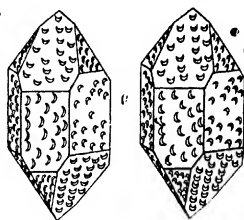

FIG. 40.—Corrosion Figures of Quartz with Hydrofluoric Acid.

studied by F. Leydolt,⁶ G. A. F. Molengraaff, J. Beckenkamp, A. Stelzner, F. Gonnard, S. Ichikawa, O. Meyer and S. L. Penfield, A. Bömer, A. C. Gill, F. Salm-Horstmar, etc.; with a soln. of *potassium or sodium carbonate*, by G. A. F. Molengraaff; with a soln. of *potassium hydroxide*, by O. Mugge, H. Baumhauer, and J. Beckenkamp; with a soln. of *sodium silicate or sodium borate*, by G. Spezia; with a soln. of borax under press., by G. Lincio; and with *water* under press., by G. Spezia. C. Friedel also examined the corrosion figures produced on β -quartz by fused *potassium hydrosulphate* at 600°. K. Jimbo, and S. Ichikawa discussed the natural etching of quartz.

In the Arabian *The Book of the Best Things for the Knowledge of Mineral Substances*, by Abu-r-Raihan,⁷ written towards the end of the tenth century, the **specific gravity** of rock crystal is stated to be 2.50; and another Arabian writer, Al-Khazini, in his *Book of the Balance of Wisdom*, written in the twelfth century, gave 2.88 for the sp. gr. of what is thought to be rock crystal. R. Boyle,⁸ in 1690, gave 2.650, and D. G. Fahrenheit, in 1726, gave 2.669. A. le Royer and J. B. A. Dumas gave 2.652 at 4° in vacuo; C. J. St. C. Deville, 2.656; W. H. Miller, 2.65259 at 18°; F. G. Schaffgotsch, 2.653 at 13° (mean of 5); T. Scheerer, 2.653; A. Liversidge, 2.683 at 20°; A. L. Dug and E. S. Shepherd, 2.650 at 25°; L. Ahlers, 2.6507-2.6528 at 0°/4°; J. Joly, 2.649-2.652 at about 14°/4°; R. Weber, 2.638; A. S. Herschel and co-workers, 2.54; A. Bartoli, 2.63; and F. C. Neumann, 2.61. F. S. Beudant gave 2.6354 and 2.6541 for the extremes of eleven determinations. L. Ahlers measured the sp. gr. of quartz. H. C. Dibbits gave:

Sp. gr.	0°	5°	10°	15°	20°	25°	30°	50°	100°
	2.6507	2.6502	2.6498	2.6493	2.6488	2.6484	2.6479	2.6460	2.6409

A. Breithaupt gave for amethyst, 2.659-2.744; for smoky quartz, 2.651-2.658; for rose quartz, 2.651-2.658; and for milky quartz, 2.618. A. Forster said that the sp. gr. of a sample of smoky quartz was 2.6503 at 0°, and after decolorization by heat, 2.6502. The Earl of Berkeley's values ranged from 2.6484-2.6487 for temp. between 21.24° and 21.95°. A. W. Warrington gave 2.650457 \pm 0.000013 at 0°; and the vol., v , at θ° , is $v = v_0(1 + 0.0433669\theta + 0.03127\theta^2)$, when v_0 is the vol. at 0°. For the sp. gr. of tridymite, G. vom Rath gave 2.295-2.326 between 15° and 16°; 2.282 at 18.5°; 2.247 for asmanite; and 2.166 for a sample of tridymite from Csik-Sz-Domokos in Hargitta Gebirge. A. Baltzer gave 2.208 for a sample from Lipari; and A. Weisbach, 2.274-2.278 for a sample from the Rittersgrün meteorite. A. Koch gave 2.43 for the sp. gr. of tridymite. G. Rose gave for artificial tridymite 2.311-2.373; P. Hautefeuille, 2.30 at 16°; and A. L. Day, 2.328-2.326. H. Steinmetz said that when α -tridymite changes to β_1 -tridymite

at 115°, its vol. expands 0.6 per cent. According to E. Mallard, the sp. gr. of cristobalite is 2.34, a little higher than the value for tridymite; P. Gaubert gave 2.348; and G. vom Rath, 2.27. The mean sp. gr. of eleven samples of artificial calcined silica was found by F. G. Schaffgotsch to be 2.20 at 12.5°, and F. Ullik gave 2.323. E. W. Washburn and L. Navias gave for the sp. gr. at 25°/25° of raw chalcedony, 2.85-2.61; raw flint, 2.61-2.63; quartz, 2.65; calcined chalcedony, 2.175; calcined flint, 2.25; cristobalite, 2.33; tridymite, 2.27; and silica-glass, 2.194-2.218. C. J. St. C. Deville found that the sp. gr. of crystalline silica, 2.656, fell to 2.22 after fusion. W. A. Shenstone gave 2.21 for the sp. gr. of vitreous silica or quartz glass; A. L. Day and E. S. Shepherd gave 2.213; and F. A. Schulze, 2.22. C. Doelter gave for the best representative values:

	Quartz	Tridymite	Cristobalite	Opal	Quartz glass
Sp. gr.	2.65	2.31	2.30	2.20	2.20

J. Johnston and L. H. Adams measured the sp. gr. of quartz and concluded that when homogeneous material free from cracks and cavities is powdered, the change of density thereby produced is but little greater than the error of the method of measurement. E. W. Washburn and L. Navias found the sp. gr. of calcined chalcedony to be raised about 2 per cent. when the material is very finely powdered. They attribute this to the opening up of pores previously sealed from access by the liquid by which the sp. gr. was determined. It is, however, also probable that the increase is due to contamination from the vessels in which the material was ground. Similar remarks, but in the converse direction, apply to the reduction in the sp. gr. of quartz ground in an agate mortar observed by P. C. Ray. The hardness of quartz,⁹ tridymite, and cristobalite is 7.0 (the diamond, 10); chalcedony is a little softer. According to F. Auerbach, the hardness of quartz on a face, parallel to the *c*-axis, is in absolute numbers, 308 kgrms. per sq. mm. (2, 20, 7), and if vertical to that axis, 230 (diamond, 2500). H. Rose said that the hardness of quartz glass is fully equal to that of rock crystal; and, according to W. A. Shenstone, the hardness lies between that of feldspar and chalcedony. According to M. Herschkowitsch, quartz glass has a hardness of 233 kgrms. per sq. mm. (diamond, 2500). R. Franz gave for the relative hardness (corundum 1000), 667; F. Auerbach, 268; A. Rosival, 176; T. A. Jaggar, 49; and F. Pfaff, 390. The subject was discussed by A. Reis and L. Zimmermann. C. Johns and C. H. Desch showed that silica glass is harder than crystalline quartz. P. J. Holmquist investigated the abrasive hardness with carborundum of different grain-size. He also found that with the (0001)-face as standard for the abrasive hardness, 1000, that for the (10 $\bar{1}$ 0)-face was 900; and for the (10 $\bar{1}$ 1)-face, 840. C. E. Guye and A. Morein studied the viscosity of quartz threads.

The elasticity of quartz with respect to sound-figures was studied by F. Savart.¹⁰ He cut circular plates parallel or perpendicular to the principal axis, and also planes parallel to cleavage faces; he found that the elasticity of all the diameters of any plane perpendicular to the principal axis is sensibly the same; planes parallel to the axis are not the same, but if three planes be taken which form equal angles with each other, the elasticity is the same. According to W. Voigt, the modulus of elasticity of quartz is 13,050 kgrms. per sq. mm. at -45°; 10,304 at 0°; 8405 at 45°; and 7853 at 90°. F. Auerbach gave 10,300 at 0°. At ordinary temp., C. E. Guye and V. Frederickz found the elastic modulus decreases with a fall of temp.; with metals, the reverse usually obtains. On the other hand, A. Perrier and B. de Mandrot found that the elasticity of quartz decreases as the temp. rises to 575°; beyond that, the elasticity at first increases very greatly for small increments of temp., and then gradually diminishes. They gave in kilograms per sq. mm., parallel to the optic axis, 10,480 at 18°; 6960 at 572°; 6510 at 574°; 6320 at 574.5°; 6020 at 575°; 6680 at 576°; 9060 at 577.5°; and 9910 at 1078°; in a direction perpendicular to the optic axis, 8010 at 18°; 3570 at 573°; 3210 at 574°; 9030 at 576°; 10,530 at 585°; and 12,190 at 1140°. A. Blackie found that the samples

of commercial quartz glass had a tensile strength varying from 281 to 902 kgms. per sq. cm., and in all cases after heating for definite periods to temp. between 1124° and 1353° , the strength fell considerably owing to devitrification by the growth of tridymite. W. Voigt gave for the **tensile strength** parallel to the chief axis, 16.3 kgms. per sq. mm., and vertical to that axis, 12.6 kgms. per sq. mm.; and for the **crushing strength**, 182 kgms. per sq. mm., and 160 kgms. per sq. mm. vertical to that axis. K. Rinne gave 153.64 kgms. per sq. mm. G. Berndt gave 25,000 kgms. per sq. cm. for the crushing strength of quartz parallel to the optic axis, and 22,800 kgms. per sq. cm. perpendicular thereto. F. Stumpf measured the elastic constants of quartz glass; and S. N. Petrenko, the behaviour of quartz glass under compressive tests. F. A. Schulze found the elasticity of quartz glass to be less than that of quartz. A. A. Griffith found the tensile strength of fresh fibres of fused quartz diminishes in a few hours to its normal value. This is explained by the formation of ultra-microscopic cracks. A. Mallock obtained for the elastic modulus of quartz in the direction of the axis 7.46×10^{11} dynes per sq. cm.; for smoky quartz, 1.207×10^{12} , and for agate, 6.381×10^{11} . W. Voigt also found for the coeff. of torsion of quartz 8405 kgms. per sq. cm. and 5085 kgms. per sq. mm. for the **torsion modulus** at 0° , and 3481 at 90° ; F. Auerbach gave 6900. F. Auerbach, and F. A. Schulze gave 6970 kgms. per sq. mm. for the elasticity of quartz glass when the value for quartz crystals is 10,620 kgms. per sq. mm. when parallel to the principal axis, and 8566 when vertical thereto. F. Horton found the torsion modulus of quartz-glass at 15° is 3.001×10^{11} dynes per sq. cm., and at 1060° , almost zero. F. A. Schulze gave 6238 kgms. per sq. mm. for the elastic modulus; R. Threlfall, 5180; and C. V. Boys, 6000. A. Pazziani and C. E. Guye studied the torsion modulus of quartz-glass fibres, and the effects of annealing. According to R. Threlfall, and C. V. Boys, the rigidity of quartz-glass fibres at 22° is 2.8815×10^{11} dynes per sq. cm.; Young's modulus, 5.1785×10^{11} dynes per sq. cm.; the bulk modulus, 1.435×10^{11} dynes per sq. cm.; and the limit allowable twist is approximately one-third of a turn per cm. in a fibre 0.01 cm. diam. W. Voigt found the **compressibility** coeff. of quartz to be $\beta = 2.65 \times 10^{-6}$, about one-twentieth of the value for water; for quartz glass, the value is 1.925×10^{-6} . A cm. cube could support a weight of 182 kgms. per sq. mm. parallel to the axis, and 160 kgms. vertical to the axis, without fracture. E. Madelung and R. Fuchs gave 2.66×10^{-6} ($p=125$ atm.); and L. H. Adams, E. D. Williamson, and J. Johnston gave 2.31×10^{-6} to 2.7×10^{-6} between 0 and 10,000 megabars. A. Schidloff and M. A. Klotz found 1.925×10^{-6} for the compressibility of quartz glass; E. Madelung and R. Fuchs gave 2.69×10^{-6} ($p=125$ atm.); and L. H. Adams, E. D. Williamson, and J. Johnston, 3.1×10^{-6} from $p=0$ to $p=10,000$ megabars. S. Ichikawa studied the lustre and brittleness of quartz.

According to H. Fizeau,¹¹ the **coefficient of thermal expansion** of quartz for the temp., θ , is $(771.1 + 1.712\theta)10^{-8}$ if measured vertical to the c-axis, and $(1316.2 + 2.526\theta)10^{-8}$, if measured parallel to the c-axis. H. Kopp gave 0.000039-0.000042 for the coeff. of cubical expansion of quartz. R. Benoit gave for the coeff. of linear expansion parallel to the chief axis, 0.0_5748 , or, at θ° , $\alpha \times 10^9 = 7110.7 + 17.12\theta$; H. Fizeau gave 0.0_5781 at 40° ; K. Scheel, 0.0_5747 ; and O. Weigel, 0.0_5737 ; and perpendicular to the chief axis, H. Fizeau gave 0.0_41419 at 40° ; R. Benoit, 0.0_40371 at 20° , or, at θ° , $\alpha \times 10^9 = 13162.7 + 25.26\theta$. For the length, l , of quartz at θ° between room temp. and 100° , when the length at 0° is l_0 , K. Scheel gave $l=l_0(1+7.144 \times 10^{-6}\theta+0.00815 \times 10^{-6}\theta^2)$; H. Fizeau, $l=l_0(1+7.10 \times 10^{-6}\theta+0.00885 \times 10^{-6}\theta^2)$; R. Benoit, $l=l_0(1+7.161 \times 10^{-6}\theta+0.00801 \times 10^{-6}\theta^2)$; and E. Reimerdes, $l=l_0(1+6.925 \times 10^{-6}\theta+0.00819 \times 10^{-6}\theta^2)$; H. McA. Randall represented the coeff. of expansion by $\alpha \times 10^8 = 717.0 + 1.620\theta$ up to 250° , and by $\alpha \times 10^8 = 1125.0 + 1.65(\theta-250) + 0.00566(\theta-250)^2 + 0.000134(\theta-250)^3$, between 250° and 470° . A. Müller gave for quartz parallel to the chief axis, $10^9(l-l_0)/l_0$, $7.067\theta + 0.008362\theta^2$ between 0° and 360° ; $3628 + 13.00(\theta-360) + 0.01852(\theta-360)^2 + 0.0_46721(\theta-360)^3$; and from 500° - 540° , $5893 + 23.07(\theta-500) + 0.1031(\theta-500)^2$.

H. le Chatelier has measured this constant over a range extending from 270°–1060°, and has shown, in his memoir, *De l'action de la chaleur sur le quartz*, that with quartz there is an abrupt change between 480° and 570°, corresponding with a change in the index of refraction. The thermal expansion of quartz in mm. per 100 mm., in passing from 270°–1060°, and starting from zero at 0°, is:

	270°	480°	570°	680°	750°	910°	1060°
Parallel to c-axis . . .	0.20	0.55	0.93	0.99	0.95	0.87	0.89
Vertical to c-axis . . .	0.42	0.86	1.45	1.59	1.59	1.57	1.55
Mean expansion . . .	—	1.76	1.28	1.39	1.40	1.34	1.33

If l represents the expansion in unit length then at θ° below 570°, the expansion of quartz perpendicular to the principal axis is $l \times 10^5 = 1.35\theta + 0.000921\theta^2$; and parallel to the principal axis, $l \times 10^5 = 0.711\theta + 0.000856\theta^2$. R. Benoit gave for the former case $l \times 10^5 = 1.316\theta + 0.00126\theta^2$, and for the latter case, both observers obtained the same result. At 570°, there is an abrupt reversible change of vol. such that unit length becomes 1.0116 perpendicular to the principal axis, and 1.0068 parallel to that axis. Above 570°, there is a contraction such that perpendicular to the chief axis $l = 0.0162 - 0.0000009(\theta - 570)$, and parallel to that axis, $l = 0.0102 - 0.0000037(\theta - 570)$. P. Braesco, A. Müller, and R. Blackie made observations on the thermal expansion of quartz, etc. P. Braesco found that precipitated silica, when dehydrated by heating only to 600°, behaves like silica glass in having only a small coeff. of thermal expansion, and therefore behaves like amorphous silica; but when heated to 1000°–1600° it behaves just like cristobalite. H. le Chatelier's results for quartz, tridymite, amorphous silica, and calcined chalcedony are plotted in Fig. 41, with temp. as abscissæ, and the percentage expansions as ordinates. The abrupt change in the vol. of quartz when it is heated to 575° corresponds with the transition of α -quartz into β -quartz as indicated above. R. Sahnien and G. Tammann gave 500°–550° for the transition temp., and G. Stein, 552°.

O. Mügge made observations on this subject. Below the transition temp., the vol. increases with a rise of temp.; above that temp. the vol. decreases with rise of temp. There are other transition points not shown on this diagram because the speed of the change is so slow, and their existence has been demonstrated by other methods. When a large piece of rock crystal is heated to a high temp. it breaks into small pieces, unless the temp. rises very slowly past 575°, because not only does the unequal expansion in different directions set up strains, but because of the abrupt increase in the expansion coeff. at about 575°. The expansion of tridymite in mm. per 100 mm. is:

	15°	95°	130°	170°	245°	480°	700°	900°	1050°
Expansion . . .	0	0.16	0.22	0.42	0.63	0.95	0.08	0.07	0.05

The abrupt change, about 130°, according to H. le Chatelier, or between 115° and 120°, according to C. N. Fenner, corresponds with a change from the form, called α -tridymite, to the other form, called β_1 -tridymite, which has optically different properties. According to C. N. Fenner, at about 162°, there is another transformation of the β_1 -tridymite into a third form of tridymite, called β_2 -tridymite. H. le Chatelier measured the expansion of quartz which had been calcined in a steel furnace, at 1500°–1600°, when the sp. gr. had fallen to 2.2, and there were no signs

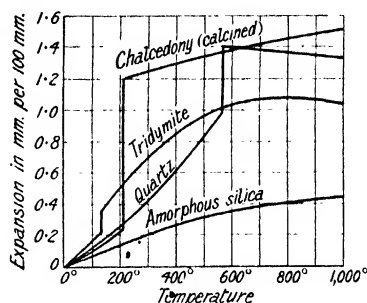

FIG. 41.—Expansion of Different Forms of Silica with Rise of Temperature.

of crystallization in the product; hence he called it *la silice amorphe*. He found for the expansion in mm. per 100 mm.:

	15°	270°	570°	660°	990°
Expansion . . .	0	0.20	0.35	0.41	0.45

The results are plotted in Fig. 41. For calcined chalcedony, he also found

	15°	95°	170°	245°	360°	650°	1050°
Expansion . . .	0	0.06	0.20	1.23	1.29	1.40	1.53

There is therefore an abrupt change between 170° and 245°, as illustrated by Fig. 41. Measurements with a dilatometer gave 210° for the transition temp. E. W. Washburn and L. Navias found for the cubical expansion, in c.c. per gram per degree, of quartz 0.25×10^{-4} near 575°; -0.049×10^{-4} near 570°; calcined chalcedony, 1.4×10^{-4} near 220°; calcined flint, 1.4 ± 10^{-4} near 227°; cristobalite, 1.5 ± 10^{-4} near 244°; and tridymite, 0.15 ± 10^{-4} near 117°. B. Bogitch made some measurements on the expansion of silica at temp. up to 1000°.

The coeff. of thermal expansion of quartz-glass is very small. H. le Chatelier¹² gave 0.067; and L. Holborn and F. Hennig gave 0.0000054 between 0° and 1000°, Fig. 41. F. Hennig found a porcelain rod, one metre long, expanded 4.271 mm. when heated from 16° to 1000°, whereas a quartz-glass rod, under similar conditions, expanded 0.531 mm. K. Scheel found that vitreous quartz between -190° and -46° contracts, not expands, and that the contraction is not overtaken at 16°. He found that two-metre rods, from two commercial samples of quartz-glass, when heated from -190°-16° were less than a metre long, for they appeared to have contracted 0.041 mm. and 0.015 mm. respectively, and when heated from 0°-100°, they expanded respectively 0.047 mm. and 0.050 mm. K. Scheel represents the length of a quartz-glass rod at a temp. θ° between 0° and 100° by $l_0(1 + 0.00000322\theta - 0.0000000147\theta^2)$, where l_0 represents the length of the rod at 0°. P. Chappuis gave $l = l_0(1 + 0.00384741\theta + 0.001150\theta^2)$. S. Valentiner and J. Wallot obtained a minimum vol. with silica-glass at -75.4°. G. E. Merritt also found a contraction with rise of temp. from -200° to -70°, and above that an expansion. The following coeff. of thermal expansion show the relation of vitreous quartz to crystalline quartz, to porcelain, and to glass:

Quartz	Quartz glass	Ordinary glass	Jena zinc borate glass	White Tübingen glass	Berlin porcelain
Parallel c-axis	Vertical c-axis				
0.0781	0.01419	0.059	0.083	0.0336	0.0938
		0.059	0.083	0.0336	0.0314

According to G. W. C. Kaye,¹³ the maximum density of quartz glass lies near -84°; the sp. gr., at ordinary temp., is near 2.22. When a glass vessel has been heated it does not at once contract to quite its original volume on cooling back to its former temp., but it suffers a slow contraction—*after contraction*, or *Nachwirkung*. This phenomenon is shown by the displacement or depression of the zero after a glass thermometer has been heated, and its gradual restoration after standing some months; and also by the gradual elevation of the zero of thermometers whose scale has been fixed before the glass has had time to season. According to A. Kuhn, quartz-glass does not show this phenomenon.

H. de Sénarmont¹⁴ measured the isothermal ellipsoids in quartz and, expressing the results in mm., found:

Major axis	9.75	10.00	11.60	12.50	13.75	15.00	18.00
Minor axis	7.50	7.50	8.50	9.75	10.00	12.00	14.00
Ratio	1.30	1.33	1.35	1.28	1.38	1.28	1.29

Measurements were also made by E. Jannettaz, and W. C. Röntgen; the latter showed that the larger the ellipsoidal figure the smaller the ratio of the two axes. D. Forbes' measurements of the **thermal conductivity** were not satisfactory; R. Weber found 0.0158 cal. per cm. per sec. per degree at 0°, and a temp. coeff. of -0.0019. The heat conductivity of quartz is greatest along the chief axis. A. Tuschschmidt's values are 0.0263 unit parallel to the axis, and 0.0160 unit

vertical to that axis at 17° . C. H. Lees obtained 0.030 and 0.016 respectively; E. Griffiths and G. W. C. Kaye, 0.0244 and 0.0147 respectively; and O. S. Buckner, 0.00099 for silica bricks. A. S. Herschel and co-workers obtained 0.0024 unit for the thermal conductivity of flint, and R. S. Hutton and J. R. Beard, 0.00060 for quartz (Calais) sand. Observations were made by M. Smoluchowsky, A. Eucken, and V. von Lang. According to A. Eucken, quartz-glass at 0° has 7.5 times less conductivity than the crystals, and at -190° , 55 times less. R. S. Hutton and J. R. Beard obtained 0.00051 for the conductivity of fused quartz. P. Gilard summarized the literature on the thermal conductivity of silica bricks—*vide* clays. Observations on this subject were made by E. Griffiths, A. T. Green, W. Nusselt, S. M. Marshall, E. Heyn and co-workers, P. Goerens and J. W. Gilles, B. Dudley, Y. Tadokoro, S. Wologdine, G. Dougall and co-workers, R. A. Horning, and G. H. Brown.

F. E. Neumann¹⁵ gave 0.1883 for the specific heat of quartz between 14° and 100° ; H. V. Regnault, 0.19132 between 13° and 99° ; H. Kopp, 0.180–0.190 between 20° and 50° ; J. Joly, 0.1881 between 12° and 100° ; A. Herschel and co-workers, 0.18 for quartz, and for various sandstones, 0.18–0.28; J. Pionchon, $0.1737+0.000394\theta-0.0.27\theta^3$ below 400° , and 0.305 between 400° and 1200° ; R. Ulrich, 0.1909 between 14° and 98° ; R. Weber, $0.1754+0.0004\theta$; K. Schulz, 0.1875 for Mamorian quartz between 20° and 100° , and 0.1871 for Brazilian quartz between 20° and 100° ; 0.2086 between 20° and 250° ; and 0.2253 between 20° and 410° . A. Bartoli gave 0.191 between 23° and 100° ; 0.241 between 28° and 312° ; 0.308 between 29° and 417° ; and 0.316 between 30° and 530° ; and H. Stierlin, 0.2030 between 20° and 138° , and 0.2472 between 20° and 609° . A. Magnus, K. Bornemann and O. Hengstenberg, and A. Dannholm made observations on the sp. ht. of quartz and amorphous silica. W. P. White found for the atomic heat (*i.e.* sp. ht. \times mol. wt. divided by the number of atoms in molecule) between 0° and

	100°	300°	500°	700°	900°	1100°	1300°	1400°
Quartz	3.755	4.359	4.784	5.112	5.217	5.308	—	—
Quartz glass	3.708	4.272	4.627	4.870	5.049	—	—	—
Cristobalite	3.784	4.689	4.876	5.042	5.163	5.276	5.351	5.388

The sp. ht. between 0° and 500° for quartz is represented by $0.1685+0.000194\theta-0.0.11\theta^2$, and for quartz glass, $0.1670+0.000189\theta-0.0.125\theta^2$. For the at. ht. (sp. ht. $\times 20.1$) at the given temp., W. P. White gave:

	0°	100°	300°	500°	700°	900°	1100°	1300°
Quartz	3.37	4.10	5.10	5.90	5.46	5.66	—	—
Quartz glass	3.33	4.05	4.95	5.35	5.58	5.75	—	—
Cristobalite	—	—	—	—	5.65	5.67	5.77	5.86

I. Iitaka found for the sp. ht. of silica-glass:

Sp. ht.	135°	180°	384°	466°	493°	573°	766°
	0.197	0.199	0.220	0.224	0.230	0.247	0.258

R. Wietzel measured the mean sp. ht. between 0° and θ° ; and his data are indicated in Table III. At high and low temp., quartz glass has the greatest sp. ht., as it should have, being the modification stable at the higher temp., but over a wide range it has a lower sp. ht. than quartz and cristobalite, and below 575° , cristobalite has a lower sp. ht. than quartz. The sp. ht. of quartz before the transformation at 575° was 0.2480, and after the transformation, 0.2527. The at. ht. are indicated in Fig. 42. F. Simon gave for the mol. ht. of quartz glass at 18.9° K., 0.107, and at 287.6° K., 3.454; for cristobalite at 28.6° K., 0.208, and at 116.6° K., 1.560; and A. Ferrier and H. Roux, 0.307–0.312 between 428.46° and 510.07° ; 0.321–0.337 between 510.07° and 571.00° ; and 0.289–0.293 between 581.13° and 661.90° . For the difference in the at. ht. at constant press. and constant vol. calculated from the expansion, W. P. White gave for quartz:

	100°	300°	500°	550°
$(C_p - C_v) \times 20.1$	0.0463	0.1313	0.802	3.832

TABLE III.—MEAN SPECIFIC HEATS OF SILICA
(in gram-cals. between 0° and θ°).

θ	Quartz glass.	Cristobalite.	Quartz.	Chalcedony.
100°	0.1850	0.1896	0.1860	0.1965
200°	0.2006	0.2125	0.2031	0.2115
225°	—	0.2196	—	—
250°	0.2068	0.2268	0.2111	0.2170
400°	0.2229	0.2417	0.2288	0.2325
565°	—	—	0.2470	—
575°	0.2366	0.2507	0.2480	0.2510
600°	0.2385	0.2521	0.2530	0.2523
800°	0.2506	0.2601	0.2585	0.2590
1000°	0.2584	0.2656	0.2630	0.2633
1200°	0.2621	0.2702	0.2661	0.2695
1400°	0.2691	0.2737	0.2690	—
1600°	0.2777	0.2783	0.2710	—
1700°	0.2810	0.2770	0.2720	—

R. Wietzel calculated the free energy of the different phases of silica. The sp. ht. of chalcedony increases more with rise of temp. than does quartz. P. Laschtschenko found the sp. ht. of quartz, at the given temp., to be :

Sp. ht.	200°	300°	405°	550°	600°	700°	800°	892°
	0.2250	0.2255	0.2306	0.2350	0.2400	0.2479	0.2471	0.2476

and that of chalcedony at 139° to be 0.1930; at 203°, 0.1961; at 227°, 0.2039;

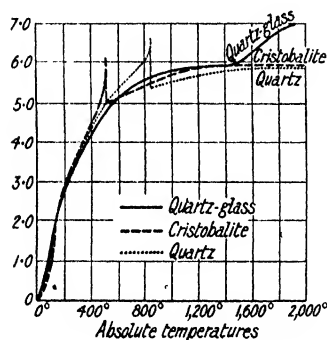

FIG. 42.—The Atomic Heats of Quartz, Cristobalite, and Quartz Glass

θ	77°	90°	218°	314°	411°	512°	704°	900°
Sp. ht.	0.15283	0.19084	0.20501	0.21418	0.22388	0.23213	0.24243	0.25043

or $0.167851 + 0.0352674\theta - 0.0640744\theta^2 + 0.03173196\theta^3$. C. Dieterici gave $0.16791 + 0.000350\theta - 0.03075\theta^2$ at θ° between 100° and 300°; and for the sp. ht. between 18° and θ° , $0.1676 + 0.00016\theta$ for temp. up to 100°, and $0.16791 + 0.0001750\theta - 0.061025\theta^2$ for temp. between 100° and θ° up to 300°. Measurements between 0° and 320° were made by J. Heinrichs. Observations on commercial silica bricks were made by E. Heyn and co-workers, Y. Tadokoro, W. Steger, and L. Bradshaw and W. Emery. G. Tammann and H. Dickmann found that, at 105°, superimposed mercury begins to penetrate powdered quartz.

In 1766, J. P. J. d'Arcet¹⁶ melted quartz sand and silica at the highest temp. of a wind furnace. About 1802, R. Hare melted quartz in the flame of the oxy-

hydrogen blowpipe, and A. Marcet, J. Mantell, F. Stromeyer, and E. D. Clarke found that all the different varieties of silica can be fused in the flame of a spirit-lamp fed with oxygen gas, or in the oxyhydrogen blowpipe flame. H. Davy fused it electrically. A. Gaudin showed that fused silica can be drawn out into long threads like molten glass—*vide infra* quartz glass. According to R. Cusack, quartz begins to soften at 1406°, and its **melting point** is 1425°. A. Lampen said that the edges of a piece of quartz are rounded at 1650°, and it fuses at 1700°. A. Bruni gave 1780° for the m.p.; W. C. Roberts-Austen, 1775°; W. Hempel, 1685°; and O. Boudouard, 1830°. A. L. Day and E. S. Shepherd, and R. B. Sosman gave 1625° for the m.p. of quartz, but it is not clear to which form this constant refers. A. Wietzel found the m.p. of quartz without conversion to cristobalite, to be between 1600°–1670°. A. Dufour said that before melting, silica becomes viscid; and G. Stein, that at 1600° silica is very viscid, but it becomes much less viscid at 1750°. L. Baraduc-Muller said that silica is not deformed at 1650°, but it begins to soften between 1702° and 1706°. These determinations are extraordinarily divergent. The equilibrium condition of all the different forms of crystalline silica, between 1470° and the m.p., is β -cristobalite. Hence, the m.p. of quartz cannot be obtained if the temp. be raised slowly enough to allow these different transformations to be completed, under these conditions, the observed m.p. must really be that of β -cristobalite; and generally, the observed m.p. of quartz must depend on the rate at which quartz is converted into its various transition forms, which, in turn, depends on the rate of heating, and the nature of what might be called impurities which act as mineralizing agents. The heating curve of vitreous silica or silica glass shows none of these changes, and it begins to lose its form about 1625°. If, however, this substance were kept long enough in any particular region of temp. it would probably pass into the form stable at that temp. C. N. Fenner gave 1470° for the m.p. of quartz; and 1625° for the m.p. of cristobalite. K. Endell and R. Rieke gave $1685^\circ \pm 10^\circ$ for the m.p. of cristobalite; N. L. Bowen confirmed this value; A. Wietzel obtained 1696°; and H. le Chatelier, 1780°. O. Ruff and P. Schmidt said silica melts as α -cristobalite at $1696^\circ \pm 10^\circ$. C. N. Fenner said that H. le Chatelier's value must be high because cristobalite can be fused to a glass in a platinum crucible, whereas the m.p. of platinum is 1755°. J. B. Ferguson and H. E. Merwin gave $1670^\circ \pm 10^\circ$ for the m.p. of cristobalite and $1710^\circ \pm 10^\circ$ for the m.p. of tridymite. P. D. Quensel gave 1550° for the m.p. of tridymite; and C. Doelter, 1575°–1580°.

C. N. Fenner's values for the **transition temperatures** of the different forms of silica are indicated in Fig. 26. For α -quartz $\rightleftharpoons \beta$ -quartz, H. le Chatelier gave 575°; F. E. Wright and E. S. Larsen, 575°; R. von Salmen, 500°–550°; and G. Stein, 552°. C. N. Fenner found the transition point rises 0.01° per atm. rise of press. For the transformation β -quartz $\rightleftharpoons \beta_2$ -tridymite, C. N. Fenner gave 870°; and A. L. Day, 800°. C. N. Fenner estimated that this transition point rises 0.10537° per atm. rise of press. For the transformation β -tridymite $\rightleftharpoons \beta_1$ -tridymite, E. Mallard gave 130°; H. Steinmetz, 115°; F. E. Wright, 120°; and C. N. Fenner, 115°–120°. For the transformation β_1 -tridymite $\rightleftharpoons \beta_2$ -tridymite, C. N. Fenner gave 163°. For the transformation α -cristobalite $\rightleftharpoons \beta$ -cristobalite, E. Mallard gave 175°; F. E. Wright, 225°; C. N. Fenner, 240°–274°; and K. Endell, 230°. For the transformation β_2 -tridymite $\rightleftharpoons \beta$ -cristobalite, C. N. Fenner, and N. L. Bowen gave 1470°, the transition temp. with chalcedony is between 170° and 245°, according to H. le Chatelier, and 173°, according to G. Stein. The relation between the m.p. and the transition temp. was studied by R. Lorenz and W. Herz.

The latent heats of the transformations are somewhat uncertain; and the estimates which have been made are the result of indirect computations. J. A. Cunningham¹⁷ calculated the latent **heat of fusion** of quartz to be 135 cal. per gram; and J. H. L. Vogt, 135 cal. E. W. Washburn calculated 6.8 Cal. per mol. for the latent heat of fusion of cristobalite. From D. Tschernobaeff's data for the heats of the reactions $\text{SiO}_2 \text{ sand} + \text{Na}_2\text{CO}_3 = \text{Na}_2\text{SiO}_3 + \text{CO}_2 - 30.4$

Cals., and $10\text{SiO}_2 + \text{Na}_2\text{CO}_3 = (9\text{SiO}_2, \text{Na}_2\text{SiO}_3)_{\text{glass}} + \text{CO}_2 - 96$ Cals., M. W. Travers obtained -7.3 Cals., and R. C. Ray, 6.95 Cals., for the heat of transformation $\text{SiO}_{2\text{cryst.}} \rightarrow \text{SiO}_{2\text{glass}}$; at 900° R. C. Ray's value is 6.50 Cals., and at the m.p. nearly the same as at ordinary temp. C. N. Fenner obtained for the latent heat of transformation $\alpha\text{-quartz} \rightarrow \beta\text{-quartz}$, 4.0 ± 1.0 cal. W. P. White gave 4.3 ± 1.0 cal. R. Wietzel obtained $2.20\text{--}2.35$ Cals., and O. Mühlert 2.21 Cals., for the heat of crystallization of quartz and chalcedony; and -0.06 for the heat of crystallization of cristobalite.

In 1806, L. N. Vauquelin,¹⁸ and in 1814, J. MacCulloch, reported that silica could be volatilized, while in 1840, J. Jeffreys claimed to have volatilized 100 kgrms. of silica by leading steam into a pottery oven at a temp. higher than the m.p. of cast-iron, but it is not clear if the white dust which was collected had not been carried along mechanically in the current of flue-gas. H. Moissan boiled silica in an electric arc-furnace and obtained a bluish-white vapour which condensed in spherical globules partly amorphous and partly crystalline. According to C. Stein, quartz begins to sublime just over its m.p., approximately 1600° . The sublimate is partly vitreous, partly flocculent silica, and partly tridymite crystals. The volatilization has been noticed at even lower temp. by E. Cramér, P. Schützenberger, E. Hirsch, L. Baraduc-Müller, etc. According to A. L. Day and E. S. Shepherd, silica-glass vaporizes copiously at the m.p. of platinum, 1755° . W. R. Mott gave 3500° for the boiling point of silica at 760 mm. O. Ruff and co-workers found silica distills rapidly at 2000° and 15 mm. press.; the vap. press. of silica was also found to be:

	1800°	1900°	1910°	2000°	2055°	2080°
Vap. press.	16	19	25	300	477	761

H. von Wartenberg has shown that a reducing gas is always present at these high temp.—free hydrogen, or hydrogen derived from carbon and steam—which reduces the silica locally, and the resulting silicon vap. burns to silica in the cooler parts of the furnace. Silicates behave in an analogous way, for the silica in them is also reduced by hydrogen almost, but not quite, as readily as free silica. The reduction of silica explains how platinum sometimes forms platinum silicide when it is heated in a reducing atm.—not in contact with the silica—presumably owing to the formation of silicon vap. or silicon hydride which attacks the platinum. Silica is also reduced by carbon, and by carbon monoxide, and a similar phenomenon then takes place. F. Kehrmann and B. Flürscheim refer to a loss of silica by evaporating an aq. soln. of an alkali silicate mixed with an excess of hydrochloric acid, but C. Freidheim and A. Pinagel show that the alleged loss by volatilization was probably incurred during filtration, not evaporation.

Crystals of quartz are uniaxial and optically positive. Quartz is doubly refracting in a direction vertical to the chief axis, and singly refracting in directions parallel to that axis; a plate cut at right angles to the chief axis is singly refracting at ordinary temp., but is doubly refracting between 560° and 580° . The refractive index of quartz is nearly the same, but rather higher than that of Canada balsam. The refractive index of the ordinary ray for sodium light is $\omega = 1.54418$, and for the extraordinary ray, $\epsilon = 1.55328$, showing that the double refraction $\epsilon - \omega = 0.009$ is low. The value of ω for smoky quartz is 1.54388 , and $\epsilon = 1.55317$. C. N. Fenner¹⁹ found that artificial crystals, obtained by heating powdered quartz with sodium tungstate for nearly a day below 865° , had the values $\omega = 1.544$, $\epsilon = 1.553$. E. Mallard gave 1.4775 for the index of refraction of tridymite with Na-light. P. Gaubert gave approximately 1.486 for the index of refraction of cristobalite for Na-light. Table IV summarizes some of the physical properties of the different forms of silica. The index of refraction is the most useful means of distinguishing these three crystalline forms of silica.

According to C. N. Fenner, the most easily determinable distinctive difference between tridymite and cristobalite is that between their indices of refraction. When tridymite is immersed in a liquid of refractive index 1.475 , tests by the half-shade method or by the Becke-line method show that the index of the material is so nearly matched that the difference

TABLE IV.—SOME PHYSICAL PROPERTIES OF THE DIFFERENT FORMS OF NATIVE SILICA.

Property.	Quartz.	Tridymite.	Cristobalite.	Chalcedony.	Opal.
Crystal system	Hexagonal	Hexagonal	Tetragonal	Rhombic	Amorphous
Axial ratios	$a:c=1:1.100$	$a:c=1:1.6530$	—	—	—
Hardness	7.0	7.0	6.0-7.0	7.0	5.5-6.5
Sp. gr.	2.65	2.28	2.348	2.6	2.1
Mol. vol.	22.8	26.3	25.7	23.23	—
Refractive index	1.549	1.4775	1.486	1.537	1.437-55
Double refraction	+0.009	+0.0021	0.00053	—	—

is scarcely appreciable. A similar test may be used for cristobalite, using a liquid of refractive index 1.485. When both are present, a liquid of refractive index 1.480 will serve to show the proportions. In making up immersion liquids for use in this manner, a soln. of potassium-mercury iodide, which is sometimes recommended, is not at all suitable, because of the change in refractive index which is likely to occur while it is being used. It is much better to make use of mixtures of albolene, the index of which ranges from 1.477 to 1.485, with kerosene ($n=1.450$) or with α -monobromonaphthalene ($n=1.658$). Albolene is a petroleum product; and the so-called Russian oil, American oil, etc., are virtually the same. Other distinctive differences between *tridymite* and *cristobalite* are that *tridymite* frequently assumes a lath-like development, and the extinction is then strictly parallel to the elongation. Wedge-shaped twins are common. With *cristobalite*, the grains are frequently elongated (perhaps an inherited property), but extinction may occur at various angles. A quite noticeable characteristic of *cristobalite* is the polysynthetic twinning, which gives several narrow stripes, as in plagioclase feldspar, or the twinning may resemble the plaid effect of *microcline*. A method of discrimination between *tridymite* and *cristobalite* of great value, depends upon the different temp. of the $\alpha\beta$ -inversions. This, however, requires the use of special apparatus.

The index of refraction of quartz has been the subject of numerous investigations. Measurements were made by F. Rudberg,²⁰ V. S. M. van der Willigen, E. Esselbach, E. Mascart, E. Sarasin, L. Mouton, C. Viola, W. Kohlrausch, G. Quincke, E. Abbe, W. Hallowell, C. Pulfrich, J. Danker, K. Zimanyi, C. Soret, A. Mülheims, H. Dufet, E. F. Martens, H. C. Sorby, H. Rubens, E. F. Nichols, E. Wülfing, etc. The index of refraction of quartz increases as the wave-length of the light used decreases. Thus J. W. Gifford found:

Wave-length (μ)	670 (Li)	643.8 (Cd)	546.1 (Hg)	480.0 (Cd)	404.6 (Hg)
Index of refraction	1.45607	1.45677	1.46016	1.46357	1.46967

L. Mouton, H. Rubens, E. F. Nichols, and E. Carvallo made observations in the ultra-red; and E. Sarasin, C. H. Simon and H. Trommsdorff, E. F. Martens, and J. W. Gifford in the ultra-violet. E. W. Washburn and L. Návias found the index of refraction of raw chalcedony to be between 1.533 and 1.538; raw flint, 1.533-1.539; quartz, 1.544-1.553; calcined chalcedony, 1.456-1.470; calcined flint, 1.438; cristobalite, 1.484; tridymite, 1.475; and silica-glass, 1.457-1.460. The effect of temp. has been studied by H. Fizeau, H. Dufet, F. Schlagdenhauffen, G. Müller, C. Pulfrich, E. Reimerdes, J. O. Reed, F. J. Micheli, etc. The index of refraction increases as the temp. rises; thus, J. W. Gifford found that ω at 18.9° is 1.5441638, and at 25.3°, 1.5441013. H. Dufet gave $-de/d\theta=0.067223+0.0637\theta$ and $-d\omega/d\theta=0.06248+0.065\theta$. E. Mallard and H. le Chatelier noticed an abrupt change in this constant at about 570°.

F. Rinne and R. Kolb's results with sodium light are illustrated by the curves, Fig. 43. According to A. N. Winchell, hexagonal crystals, exemplified by the *isotropic quartz* from Iron River, Michigan, may be

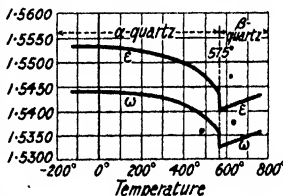

FIG. 43.—The Effect of Temperature on the Refractive Index of Quartz (Na-light).

isotropic, and the mineral furnishes X-radiograms like those of anisotropic quartz. In 1830, D. Brewster showed that quartz-glass is not doubly refracting. The index of refraction of quartz-glass has been measured by C. H. Simon and H. Trommsdorff, H. Dufet, E. F. Martens, M. Herschkowitsch, J. W. Gifford and W. A. Shenstone, and F. A. Schulze. J. W. Gifford found for light of wave-length λ , the refractive index of quartz-glass is:

λ	670.8	546.1	508.6	436.9	404.6 $\mu\mu$
Index	1.4560717	1.4601545	1.4619030	1.4667412	1.4696753

C. Hlawatsch studied the effect of colouring pigments on the refractive index and found:

	Colourless. quartz	Smoky quartz	Smoky quartz		
			Light place	Dark place	Calcined
ω	1.54433	1.54388	1.54403	1.54387	1.54436
ϵ	1.55305	1.55317	1.55299	1.55289	1.55344

The double refraction of quartz is small. The dispersion of the double refraction $\epsilon - \omega$ has been determined by M. de Lépinay, F. Paschen, L. Mouton, E. Ketteler, J. W. Gifford, J. O. Reed, G. Abati, E. F. Martens, E. Aschkinass, F. J. Michali, C. G. Knott, C. Pulfrich, etc. F. E. Wright and E. S. Larsen's data for the double refraction $\epsilon - \omega$ at different temp. are:

	15°	100°	220° *	535°	570°	590°	1060°
$\epsilon - \omega$	0.00910	0.00902	0.00882	0.00811	0.00797	0.00760	0.00787

The refraction index of tridymite is 1.477, and the double refraction is feeble and positive.²¹ In 1884, A. Merian noticed that when biaxial tridymite is warmed, it becomes uniaxial, and on cooling, the crystals again become biaxial. The mean refractive index of cristobalite for yellow light is 1.49. For artificial tridymite, prepared by heating powdered silica with sodium tungstate for about a day at about 875°, C. N. Fenner found for the refractive index parallel to the α - and β -axis 1.469, and for the γ -axis 1.473 (23°). Similarly, for cristobalite C. N. Fenner obtained for sodium light (at 23°) $\gamma = 1.487$, $\alpha = 1.484$ for artificial crystals prepared in a similar way, but at a temp. of 1475° instead of 875°. According to P. Gaubert, the double refraction of cristobalite is 0.00053 and negative. On heating to about 230°, there is an abrupt change from the doubly refracting into the isotropic crystalline variety, called β -cristobalite to distinguish it from normal or α -cristobalite. Fused quartz is not doubly refracting. A. Ehringhaus and H. Rose compared the dispersion and double refraction of silicon, titanium, and tin dioxides with the mol. wt.

In 1812, J. B. Biot²² found that crystals of quartz have the remarkable property of rotating the plane of polarization of light, transmitted in the direction of the principal axis, in such a way that in some crystals the ray is deflected to the right, and in others to the left. The former is conventionally called *right-handed quartz*, the latter *left-handed quartz*. J. B. Biot's convention as to the right- and left-handedness of quartz is now in fairly general use, although some confusion formerly prevailed, because J. Herschel reversed the convention proposed by J. B. Biot. J. Pereira said:

If, on turning the analyzing prism or tourmaline from left to right, the colours descend in Newton's scale, that is, succeed each other in this order—red, orange, yellow, green, blue, indigo, and violet—J. B. Biot designates the polarization as *right-handed*, or +, or \mathcal{R} ; whereas if they descend in the scale by turning the analyzer from right to left, he terms it *left-handed*, or —, or \mathcal{L} . Sir John Herschel, on the other hand, supposes the observer to look in the direction of the ray's motion. Let the reader take a common corkscrew, and holding it with the head towards him, let him use it in the usual manner, as if to penetrate a cork. The head will then turn the same way with the plane of polarization as a ray in its progress from the spectator through a right-handed crystal may be conceived to do. If the thread of the corkscrew were reversed, or what is termed a left-handed thread, then the motion of the head, as the instrument advanced, would represent that of the plane of polarization in a left-handed specimen of rock crystal.

J. Herschel, and D. Brewster pointed out that the **optical rotation** discovered by J. B. Biot is related with the structure of the crystals. As in the case of tartaric acid, the crystals are enantiomorphic as illustrated in Fig. 40. The rotating power is also proportional to the thickness of the plate. Observations have been made by O. Roch, V. von Lang, P. Desains, R. Dongier, etc. Lord Rayleigh studied the effect of the earth's motion on the circular polarization of quartz. For sodium light, J. Stefan found the angle of rotation of a plate one mm. thick to be 21.67° , and the angle increases with a rise of temp. from 21.599° at -20° to 25.259° at 840° . The effect of low temp. has been studied by C. Soret and C. E. Guye, J. L. Soret and E. Sarasin, etc. M. G. Levi found that a quartz plate had $\delta=99.25^\circ$ at 12° , and $\delta=102^\circ$ at -180° . The effect of temp. has been studied by V. von Lang, L. Sohncke, D. Gernez, H. Dufet, J. Joubert, etc. According to E. Gumlich, the optical-rotatory power, δ , at the temp. θ between 0° and 100° for rays of all colours, is $\delta=\delta_0(1+0.000131\theta+0.00000195\theta^2)$, where δ_0 denotes the angle of rotation at 0° . F. Burki gave $\delta=7.1505\lambda^{-2}e^{0.01864\lambda^{-1}}$; and P. Drude, $\delta=12.200(\lambda^2-\lambda_0^2)^{-1}-5.046\lambda^{-2}$. The shorter the wave-length of the light, the greater the rotation of the light, so that the angle is smaller for red than for yellow, and so on. Thus, with a plate one mm. thick, H. le Chatelier obtained the results indicated in Table V, and Fig. 44. Fused quartz does not exhibit the phenomenon of circular polarization. P. Zeeman and A. Snethlage measured the Fizeau effect with quartz.

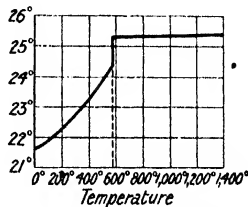

FIG. 44.--Effect of Temperature on the Circular Polarization of Light by Quartz.

TABLE V.—OPTICAL ROTATION OF QUARTZ AT DIFFERENT TEMPERATURES WITH LIGHT OF DIFFERENT WAVE-LENGTH.

Temp.	Optical rotation with light of wave-length.					
	656 Red.	589 Yellow.	518 Green.	500 Green.	448 Blue.	279 Ultra-violet.
20°	17.25°	21.72°	28.62°	30.78°	39.24°	114.5°
280°	18.06°	22.68°	29.82°	32.16°	40.80°	—
415°	18.60°	23.40°	30.60°	32.90°	42.00°	127° (475°)
560°	19.38°	24.30°	32.04°	34.56°	44.10°	—
600°	20.10°	25.26°	33.18°	35.76°	45.60°	131° (650°)
900°	—	25.82°	33.24°	36.00°	45.84°	132°

A. Fresnel,²³ V. von Lang, R. Dongier, A. Cornu, E. Brodhun and O. Strömrock, R. Brunhes, etc., have discussed the theory of the subject. The production of *Airy's spirals* when two equally thick plates right- and left-handed are superposed and examined in convergent monochromatic polarized light was described by G. B. Airy,²⁴ J. C. Jamin, B. Hecht, R. Straubel, F. Beaulard, A. Gouy, G. Quesneville, K. Schmidt, R. Ritter, etc. The **optical anomaly** of quartz was investigated by Lord Rayleigh, D. Brewster,²⁵ H. W. Dove, G. Jenzsch, A. Breithaupt, E. Reusch, H. Böklen, G. Wyruboff, R. Brauns, E. Schumacher, K. A. Lossen, E. Stecher, C. A. MacMahon, etc. Uniaxial quartz crystals become biaxial when press. is applied at right angles to the optical axis. The effect of *pressure* on the optical properties of quartz crystals was observed by D. Brewster, A. Moigno, F. Pfaff, H. Bücking, M. Sidorenko, E. Mach and J. Merten, F. Pockels, F. Beaulard, H. Monnory, and P. Dongier; the effect of *heat*, by W. Klein, and P. P. Koch; and the effect of an *electrostatic field*, by A. Kundt, W. C. Röntgen,

P. Tschermak, and F. Pockels. Uniaxial quartz crystals in the electric field change in a way analogous to that observed with compression.

In the magnetic field there is a simple rotation of the plane of polarization parallel to the axis.²⁶ The magnetic-optic rotation of quartz, that is, the rotation of a beam of polarized light in a magnetic field, expressed in the terms of E. Verdet's constant at 20°, decreases from 0.1587 for light of wave-length $\lambda=0.2219\mu$ to 0.1079 when $\lambda=0.02573\mu$; to 0.04617 for $\lambda=0.3609\mu$; to 0.2750 for $\lambda=0.4678\mu$; to 0.02574 for $\lambda=0.4800\mu$; to 0.02257 for $\lambda=0.5086\mu$; to 0.01664 for $\lambda=0.5892\mu$; and to 0.01368 for light of wave-length 0.6439μ when measured along the *c*-axis. For variations of wave-length from $\lambda=0.467\mu$ to 0.644μ , and a temp. between 20° and 96°, E. Verdet's constant is $1+0.00011(\theta-20)$ times the value of the constant at 20°. Values were obtained by J. Disch, A. Borel, and T. M. Lowry.

Light passing through a crystal is continuously absorbed as the distance traversed by the light increases. With white light, the different colours are often absorbed at different rates, and the colour of the crystal is due to a combination of the remaining colours. The two rays of a doubly refracting crystal may be absorbed differently so that the colour of the crystal appears different according to the direction in which the light is transmitted. This property is called dichroism when two colours are involved, and the general term used is pleochroism. In a polarizing microscope, with the analyzer out, the colour varies as the crystal is turned. An instrument called the *dichroscope* is designed to show the colour of the two rays of the crystal side by side. D. Brewster,²⁷ and A. Beer showed that amethyst exhibited pleochroism in that the ordinary ray appears pale reddish-violet, and the extraordinary ray, dark bluish-violet; W. Haidinger, that the ordinary ray is more strongly absorbed than the extraordinary ray with crystals from Brazil, Siberia, and from Schemnitz; and H. Baumhauer showed that this applies also with colourless quartz. J. Moreau, C. Ehlers, and P. Ites measured the different absorbing power of quartz for the ordinary and extraordinary rays. E. G. Merritt, and J. Königsberger measured the effect with ultra-red rays; and J. Königsberger, and V. von Agafanoff, the effect with ultra-violet rays.

Quartz is almost transparent to the ultra-violet rays, and, according to C. Poelter, quartz glass is rather more absorbent than the crystals. The transparency for the extraordinary ray is rather larger than for the ordinary ray, and the smaller the wave-length the greater the absorption. Thus, J. Königsberger found for the transparency of a sample of smoky quartz, expressed as a percentage value of the transparency of fluorspar:

Wave-length	1.0	1.5	2.1	2.5	3.0	3.5	4.0 μ
Ordinary ray	90	85	89	88	81	80	45
Extraordinary ray	93	92	92	91	90	80	45

E. T. Wherry,²⁸ and E. F. Holden measured the absorption spectrum of rose-quartz. The latter found rose-quartz to be pleochroic. W. R. Ham and co-workers, and G. Joos studied the ultra-violet absorption spectrum of quartz; and W. Jevons, the band spectrum. The transparency of quartz glass for ultra-violet light was studied by H. Trommsdorff, A. Pflüger, H. Kriess, R. Schachenmeister, S. B. Nicholson and E. Pettitt, and C. Schaefer and M. Schubert, J. Königsberger and W. J. Müller, H. Buisson, etc. V. Schumann measured the effect in terms of the time, in seconds, required to affect photographic plates to the same extent.

Wave-length	361	275	231	214	199 $\mu\mu$
Quartz glass	20	20	20	20	180
Air	18-19	16-17	12-13	11-12	1-2

According to W. W. Coblentz, the transmission spectrum of a plate of clear quartz cut perpendicular to the principal axis and 0.12 mm. thick shows small bands at 2.9 μ and 4.35 μ , Fig. 45. J. Königsberger with smoky quartz obtained bands at

3.05 μ and 4.05 μ ; and E. G. Merritt, with polarized light, obtained bands at 3.0 μ and 3.6 μ for the extraordinary ray and 2.9 μ , 3.75 μ , and 4.1 μ for the ordinary ray. With amethyst, J. Königsberger obtained a band at 3.1 μ . E. F. Nichols, and C. V. Raman made some observations on this subject.

W. W. Coblentz measured the **reflection spectra** of quartz and quartz glass, and found the one to be entirely different from the other, Fig. 46. The maxima in

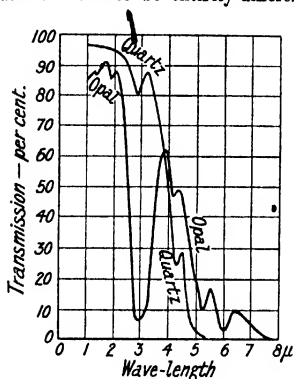

FIG. 45.—Transmission Spectra of Quartz, and of Opal.

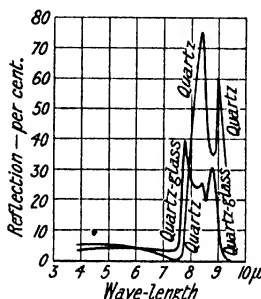

FIG. 46.—Reflection Spectra of Quartz, and Quartz Glass.

the reflection spectra of crystalline quartz occurs at 8.4 μ and 9.02 μ ; and with amorphous quartz, at 7.8 μ , 8.4 μ , and 8.8 μ . The intensity of the maxima of the bands of quartz glass is not so great as those of crystalline quartz, nor does the reflecting power in the region of the spectrum just preceding a reflection band, fall to so low a value as in crystalline quartz. H. Rosenthal made observations on this subject, and measurements of the reflection spectrum in the ultra-violet were made by O. Reinkober. E. P. Lewis and A. C. Hardy found the **reflective power** of quartz, for radiations below $\lambda=1860$, to be 9 to 10 (rock salt, 8 to 9). W. W. Coblentz found the reflecting power for light of wave-length $\lambda=0.95\mu$ to be 81 per cent.; for $\lambda=4.4\mu$, 41.5 per cent.; for $\lambda=8.8\mu$, 7.9-13.4 per cent.; and for $\lambda=24\mu$, 9.0 per cent. C. Schaefer and M. Schubert showed that quartz, chrysoprase, hoesenstein, and chalcedony have the same quantitative reflecting power, and the maximum at about 9 μ exhibits 90 per cent. of the metallic reflection. With opal and quartz glass, the reflection maximum is in the same proportion as with the other varieties of silica, but the reflecting power is 40-50 per cent. less. This is attributed to a distortion of the space-lattice in the amorphous varieties of silica. It is remarkable that the water maximum, which lies at 3.2 μ , is not observed in the case of opal, and it is hence assumed that water is not arranged in the space-lattice of opal. H. E. Ives and co-workers studied the **emissivity** and **illuminating power** of mantles made of silica and heated in the bunsen-flame. H. Rubens and E. Aschkinass measured the transparency of quartz for the so-called *Reststrahlen*.

C. F. Kunz,²⁹ E. F. Holden, and A. Lacroix noted that exposure to **light** lessens the intensity of the colour of rose-quartz. P. Villard found that colourless quartz is darkened by exposure to **cathode rays**. J. Ewles found the minimum voltage for the excitation of the blue cathodoluminescence of silica to be 750; E. L. Nichols and D. T. Wilbur also studied this subject. C. Doelter investigated the action of ultra-violet rays on the colour of quartz. J. O. Perrine observed no signs of the excitation of fluorescence by the **X-rays**. According to C. Doelter, quartz is semi-opaque to the X-rays, and its transparency lies between that of corundum and that of calcite. G. T. Beilby, C. J. Salomonsen and G. Dreyer, N. Georgiewsky, and

INORGANIC AND THEORETICAL CHEMISTRY

others found that colourless rock crystals are coloured brown by radium and X-rays, and the colour is removed by exposure to ultra-violet rays or by heating to 200°. C. Doelter and H. Sirk found that the coloration is mainly produced by the γ -rays, and also by the β -rays. Observations were also made by N. Egoroff, C. Doelter and H. Sirk, etc. M. Berthelot found that some specimens of quartz were decolorized by radium radiations, and he therefore attributed the positive instances of decoloration to the presence of an impurity. N. Egoroff, O. Hönigschmid, and C. J. Salomonsen and G. Dreyer found that colourless quartz becomes pleochroic by the action of radium rays. Rose-quartz, amethyst, cairngorm, and citrine all become colourless when heated—according to E. Newbery and H. Lupton, rose-quartz requires a red heat; amethyst requires strongly heating directly in the blowpipe-flame; and nearly black cairngorm sometimes becomes colourless when heated in a soft glass tube. They also found that when exposed to radium radiations for seven days colourless quartz becomes smoky, and the coloration penetrates a depth of one cm. into the crystal. Rose-quartz decolorized by heat became smoky rather more readily than clear rock crystal, and the pink colour was restored to some extent. Amethyst decolorized by heat did not become smoky, but the purple colour was slowly restored. K. Simon found amethyst is decolorized over 550°. E. Newbery and H. Lupton observed that decolorized cairngorm slowly regained its colour when exposed to radium radiations, and this more rapidly than with the other samples of quartz examined—*vide* 3, 26, 4. All the recoloured crystals were readily decolorized by moderately heating them, and at the same time a faint thermoluminescence appeared. F. Schröter, and E. L. Nichols and co-workers investigated the blue glow which occurs with silica heated in the oxyhydrogen flame. Observations on the action of radium rays were made by A. Ben-Saude and G. Costanzo, C. Doelter, G. O. Wild and R. E. Liesegang, and S. C. Lind and D. C. Bardwell. E. F. Holden concluded that the colour of rose-quartz is not due to radium radiations; and A. Lacroix said that rose-quartz is never associated with radioactive minerals, while smoky quartz is observed with them—a fact also noted by H. V. Ellsworth. Radium radiations may produce an effect like smoky quartz, and also like amethyst. A. Miethe did not observe thermoluminescence when smoky quartz, intensely coloured by exposure to radium radiations, was heated, but G. T. Beilby, E. Newbery and H. Lupton, V. M. Goldschmidt, etc., observed the effect. D. L. Chapman and I. J. Davies, W. E. Curtis, and E. B. Ludlam and W. West found that quartz glass acquires the power of phosphorescing, and, thermoluminescing after exposure to the electrical discharge. S. C. Lind and D. C. Bardwell studied the effect of radium radiations on quartz, chrysoprase, moss-agate, and opal. D. Hahn observed that many varieties of rock crystal give a pale yellow thermoluminescence; other varieties give a whitish shimmering glow; and an amethyst glowed with a yellowish light. The phenomenon was also investigated by J. C. y Léon, K. von Kraatz-Koschlau and L. Wöhler, etc. G. F. Kunz and C. Baskerville did not make quartz luminescent by exposure to radium radiations, X-rays, or ultra-violet light. E. L. Nichols and co-workers found that when heated to a certain definite temp. silica emits a blue glow, and the radiation is in excess of that emitted by a black body at the same temp. According to E. Rutherford, a fused quartz tube, after continued exposure to radium emanation, became brittle and cracked, and the whole tube showed a multitude of approximately circular cracks. M. S. Curie also found quartz-glass tubes cracked when exposed to the α -rays from a polonium preparation. Hence, quartz glass is very unsuited for enclosing very radioactive preparations. In 1784, G. de Razoumowsky referred to *le phosphorisme des corps du règne minéral par le moyen du frottement*, and included quartz in his list; five years later T. Wedgwood also referred to the luminosity produced in quartz by attrition; and J. H. Pott observed the same phenomenon with flint. M. Trautz observed triboluminescence with native quartz, but not with precipitated silica. E. R. Lankester, E. Heron-Allen, J. W. French, W. T. Sollas, C. C. Wilson,

A. Brammhall, G. C. G. Damant, and H. S. Allen have studied the luminosity of quartz by attrition. Many varieties of native quartz show **radioactivity**, and they contain some occluded helium and argon gases, as well as some uranium and radium. R. J. Strutt obtained the numbers indicated in Table VI. S. Ichikawa studied the relation between the colour and the phosphorescence of quartz; W. E. Curtis, the phosphorescence of silica-glass.

TABLE VI.—RADIOACTIVITY OF NATIVE QUARTZ.

Origin of quartz.	Occluded helium per c.mm.	Occluded argon per c.mm.	Radium per 100 grms. Grms.	Uranium oxide per 100 grms. Grms.	Helium per gm. U_3O_8 c.c.
Madagascar . . .	2.4	3.16	1.39×10^{-11}	4.29×10^{-5}	9.0
Ilfracombe . . .	1.43	2.5	7.45×10^{-11}	2.31×10^{-5}	10.4
Brazil . . .	0.74	2.0	—	—	—
Quartz sand . . .	0.55	—	1.94×10^{-11}	6.00×10^{-5}	6.0
Flint (Norfolk) . .	0.295	1.9	4.30×10^{-11}	1.33×10^{-4}	0.246

When certain crystals are heated in an air bath, and then drawn quickly through an alcohol flame and allowed to cool, a positive charge of electricity collects about the so-called antilogous poles. The phenomenon is called **pyroelectricity**.³⁰ The charges of electricity can be rendered evident by their effect on other charged bodies; or, according to A. Kundt, by blowing a fine spray of a mixture of equal parts of powdered sulphur and red-lead on the cooling crystal, the sulphur collects about the positive poles and the red-lead about the negative poles. The phenomenon with quartz has been investigated by S. Ichikawa, W. G. Hankel, C. Friedel and J. Curie, W. C. Röntgen, A. Kundt, C. F. Naumann, B. von Kolenko, J. Beckenkamp, and P. P. Koch. Electric charges accumulate at certain points on a crystal if it be pressed between the fingers or in other ways. The charges developed are analogous with those developed by heating the crystal, and the phenomenon is called **piezoelectricity**.³¹ The phenomenon has been investigated by J. and P. Curie, Lord Kelvin, A. Beckman, F. Pockels, W. G. Hankel, A. Kundt, W. C. Röntgen, P. Czernak, and E. Riecke and W. Voigt. A. Perrier and B. de Mandrot found the phenomenon with quartz disappears at 576°. The elastic deformation of quartz crystals by electric charges has been investigated by J. and P. Curie.³² C. Marangoni discussed the piercing of quartz plates by a high tension electric discharge.

H. F. Richards³³ measured the electrification produced by the contact of quartz with fluorite, glass, and steel. E. Warburg and E. Tétgenmeier showed that a slice of rock crystal cut perpendicularly to the principal axis, and having its ends covered with layers of gold or plumbago, when subjected at a temp. of about 230° to a long-continued e.m.f. of considerable intensity, had its **electrical conductivity** permanently reduced to a small fraction of its original amount. In directions perpendicular to the axis, rock crystal, even at higher temp., has little or no conductivity. The electrical conductivity of rock crystal in the direction of the principal axis is, at high temp., about the same as that of ordinary glass. When a slice cut perpendicularly to the axis is electrolyzed, sodium-amalgam being used as the anode, sodium migrates through the slice, its amount being in accordance with Faraday's law, and the weight of the slice remains unchanged. Even at high temp., rock crystal acts as a good insulator with respect to an e.m.f. in a direction perpendicular to the principal axis. When potassium-amalgam was used in the place of sodium-amalgam, the current had sunk after 40 hrs. to about the hundredth part of its original value, only 2 milligrams of silver in the coulometer were separated, and no potassium could be detected at the cathode, even by means of the spectroscope. It was therefore concluded that the conductivity is due to the presence of sodium, in the form of Na_2SiO_3 , which was shown by

analysis to be present in the proportion of 1 part in 2300, so that the crystal might be regarded as a very dil. soln. of this salt. The electrolytic character of the conductivity was further confirmed by the fact that a cell giving e.m.f. of from 1.3 to 2 volts could be formed of mercury, a slice of quartz at a temp. of 225°, cut perpendicularly to the axis, and sodium-amalgam. According to the ionic theory of electrolysis, the fact of electrolytic conduction taking place only in the direction of the principal axis, would tend to the inference that in the case of rock crystal not traversed by an electric current, the interchange of atoms between the mols. can only take place, at any rate to a sensible extent, in the direction of the principal axis. E. Tegetmeier showed later that lithium may replace sodium in developing the conductivity of quartz. P. Curie referred the conductivity of quartz to the presence of water or salt soln. in capillary passages oriented parallel to the chief axis; J. Beckenkamp assumed an intramolecular distribution of a fluid so that the ions of the electrolyte are disposed between the crystal mols.; and J. Bejerinck assumed that films of opal are distributed within the crystal.

According to P. Curie,³⁴ the electrical conductivity of quartz in the direction of the principal axis is 0.844×10^{-14} mho at 20°; 0.122×10^{-11} at 100°; 0.147×10^{-10} at 200°; and 0.179×10^{-7} at 300°—the resistance of mercury at 0° is 1.063×10^3 ohms. K. and F. Exner gave for the conductivity of quartz parallel to the chief axis, 0.21×10^{-9} mho at 109°, and 0.46×10^{-8} at 143°. G. Wulff measured the electrical conductivity of quartz.

E. Tegetmeier gave for the sp. electrical resistance of quartz, referred to that of mercury, as 3.55×10^{10} at 0°, 5.78×10^{10} at 100°, and 5.18×10^{10} at 1600°. E. Warburg and E. Tegetmeier obtained in the direction of the chief axis, 2×10^{11} to 7×10^{11} at 224°. K. and F. Exner obtained a resistance of 4.1×10^{15} ohms at 101° and 0.9×10^{15} at 147°; and M. von Pirani and W. von Siemens obtained 4×10^4

ohms at 1300° when that of porcelain at the same temp. is 1.7×10^4 ohms. C. Doelter obtained perpendicular to the principal axis:

	430°	605°	780°
Ohms . . .	61,400	4,080	6,690
	850°	880°	1180°
Ohms . . .	20,300	52,500	7,540

and parallel to that axis:

	930°	1020°	1140°
Ohms . . .	115,000	36,512	11,970
	1250°	1390°	1400°
Ohms . . .	6,940	3,220	3,160

Analogous results were obtained with other samples. The results are plotted in Fig. 47. The observed results were represented by E. Rasch and F. Hinrichsen's equation, $\log R = AT^{-1} + C$, where R is the resistance in ohms; T , the temp. on the absolute scale; and A and C are constants. This expression has a formal resemblance

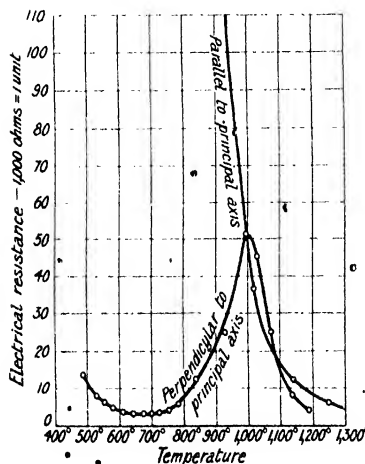

FIG. 47.—Electrical Resistance of Quartz.

to the integrated form of J. H. van't Hoff's equation $\log R/dT = -A/RT^2$ (I. 12, 9). K. and F. Exner gave 0.26×10^{-11} mho for the electrical conductivity of quartz glass at 101°, and 0.11×10^{-10} at 147°; and M. von Pirani and W. von Siemens gave 0.25×10^{-4} mho at 727°. C. Doelter gave for the sp. resistance of quartz glass:

	922°	988°	1050°	1154°	1207°
Ohms . . .	132,800	73,330	66,923	14,291	10,000

F. Horton found the effect of temp. on the electrical resistance in ohms, and the electrical conductivity in mhos of slabs of quartz-glass to be:

	468°	652°	703°	899°	1013°	1288°
Ohms	95×10^4	35×10^3	198×10^4	409000	170000	65200
Mhos	1.79×10^{-9}	4.86×10^{-3}	8.59×10^{-3}	4.16×10^{-7}	1.00×10^{-7}	2.60×10^{-6}

There is thus a rapid increase in conductivity with rise of temp. A. Jaquerod and H. Mügeli found the sp. conductivity of silica glass to be 3.1×10^{-20} mhos per c.c. at 60°; 3.16×10^{-19} at 80°; and 3.2×10^{-18} at 100°. A. Joffé showed that the electrical conductivity of quartz is increased by exposure to radium radiations, X-rays, or ultra-violet light, and the effect is greater on the conductivity parallel to the principal axis than on the conductivity perpendicular to that axis. A. Schaposchnikoff found that the electrical conductivity of quartz follows Ohm's law only with electric fields of moderate intensity; with over 4000 volts per cm. there are marked deviations. A. V. Henry measured the electrical resistance of silica refractories between 400° and 1100°.

Quartz at ordinary temp. is an electrical insulator. The **dielectric constant**—determined by M. Romich and J. Nowak,³⁵ E. Schott, P. Curie, R. Fellingner, W. Schmidt, L. Ebert, W. Voigt, F. Paschen, H. Starke, E. S. Ferry, etc.—parallel to the axis lies between 4.6 and 5.057; and at right angles to that axis, 4.32–4.695. W. M. Thornton found 4.6 parallel to the principal axis, and 4.5485 perpendicular to that axis. F. Hasenöhrle found that at a temp. θ° , the dielectric constant parallel to the principal axis is $4.926\{1 - 0.00110(\theta - 10) - 0.000024(\theta - 10)^2\}$; and perpendicular to that axis, $4.766\{1 - 0.00099(\theta - 10)\}$. The insulating properties thus decrease with rise of temp. The dielectric constant of quartz is greater than the value computed from the refractive indices; this is also the case with fluorspar, and calcspar. M. Faraday, L. Boltzmann, and H. A. Rowland and E. L. Nichols discussed the dielectric polarization of quartz. F. A. Schulze found the dielectric constant of quartz-glass to be between 3.2 and 3.4; and A. Coehn and A. Curs, 3.2–3.5. A. Jaquerod and H. Mügeli studied the anomalous charging and discharging currents in silica-glass used as the dielectric of a condenser. They also examined the effect of dissolved gases—hydrogen, and helium—on the residual currents in silica-glass. W. F. Powers measured the temp. coeff. of frequency of quartz resonators. All kinds of quartz are diamagnetic. O. Tumlirz³⁶ found quartz to be diamagnetic perpendicular to the principal axis, and W. König, E. Stenger, etc., have measured the **magnetic susceptibility**. P. Curie found between 18° and 430°, -0.44×10^{-6} mass units; S. Meyer, -0.07×10^{-6} to 0.17×10^{-6} mass units; J. Königsberger, and W. Voigt and S. Kinoshita obtained -1.2×10^{-6} vol. units at 20°. B. Bavink, and G. Wistrand have studied the magnetic properties of quartz. W. Voigt found quartz to exhibit **piezomagnetism**.

§ 19. The Chemical Properties of Silica

The general chemical properties of the different varieties of crystalline and amorphous silica are very similar; and the same remark applies also to the hydrated forms. The main difference turns on the different speeds of reaction. From this point of view the hydrates are the most active, and quartz, the least active. According to R. Schwarz,¹ amorphous silica (silica glass) is more active than cristobalite, cristobalite is more active than tridymite, and tridymite is more active than quartz. F. W. Clarke said that in all probability tridymite, cristobalite, and quartz are polymers of the fundamental mol., SiO_2 ; and tridymite and cristobalite are the less complex; and therefore more stable at high temp. They are, moreover, less dense than quartz, and quartz-glass, with a still lower density, probably approximates more nearly to the simple mol., SiO_2 . J. A. Hedvall observed that the precipitated and amorphous forms of silica react faster with the alkaline earth oxides than cristobalite, and this in turn faster than quartz—*vide infra*.

E. Wolf² examined the loss on ignition of quartz. The catalytic effect of quartz on the union of hydrogen and oxygen has been previously indicated (1, 9, 9); and the effect of silica gel at 150°, 250°, and 350° on the esterification of alcohol was found by C. H. Milligan and E. E. Reid to be twice as great as that of titanic oxide. According to P. Villard, if a tube of silica-glass attached to a manometer be exhausted and heated by a gas-flame, the press. inside rises owing to the passage of

hydrogen through the walls of the tube. M. Berthelot said that hydrogen passed through quartz-glass at 1300°, and Z. von Hirschberg, at 1000°. The permeability increases as the temp. is raised. J. B. Johnson and R. C. Burt found the diffusion of hydrogen through quartz-glass starts at 300°, and with nitrogen at 600°. H. Briggs studied the adsorption of hydrogen and nitrogen by silica. G. A. Williams and J. B. Ferguson found that one c.c. silica-glass of sp. gr. 2.22 and at 515°, dissolved 0.0095 c.c. of hydrogen (at n.p.t.) with the press. 750–760 mm. and at 445°, 0.00989 c.c. With helium, 0.0101 c.c. was dissolved at 515°, and 0.0103 at 445°. The solubilities of the gases bear no relation to the rates of diffusion through silica-glass. O. A. Hougen and B. L. Miller found that the siliconizing of platinum wires in silica-tubes in a reducing atm. above 900° is due to silicon vapour produced by the reduction of silica. A. Jaquero and F. L. Perrot found that helium diffuses perceptibly through silica-glass at 220°, and very rapidly at 1100°. The rate of diffusion is proportional to the press. G. A. Williams and J. B. Ferguson found the permeability of silica-glass for helium at 180° can be measured, and at 500°, it is about 22 times that of hydrogen. A. Piutti and E. Boggio-Lera found that at 480° helium is unable to traverse plates of *l*-quartz or *d*-quartz plates only 0.3 to 1.0 mm. thick, and cut parallel or perpendicular to the optic axes, but quartz-glass is permeable at this temp. O. W. Richardson and R. C. Ditto found neon to be rather less diffusible than helium. M. Berthelot, and Z. von Hirschberg reported that quartz-glass is permeable to oxygen, nitrogen, and methane, at 1300°. A sealed quartz-glass tube of 5 c.c. capacity, was filled with hydrogen at 0.2 atm. press. and heated for an hour at 1300°. The contents of the tube were then eq. to 0.68 c.c. of hydrogen or to 0.12 c.c. measured at atm. press. Fused-silica tubes with walls 0.7 mm. thick are not permeable to hydrogen at the ordinary temp., but become so at 800°, whilst at 1300° the diffusion is very marked; hydrogen chloride does not begin to diffuse through the walls of a quartz-glass tube below 1400°, neither does carbon dioxide below 1300°; the diffusion of nitrogen is feeble at 1000°, but becomes appreciable at 1300°–1400°, whilst oxygen diffuses more readily; relative experiments on the rates of diffusion of these two gases show that at 1400° under a press. of 1.2 atm. one-sixth of the initial vol. of nitrogen or one-third of the initial vol. of oxygen diffuses during one hour. The quartz-glass tubes suffer a permanent distension from the effect of the increased internal press. at the high temp. It was found that tubes of ordinary white glass or of Jena glass are permeable to hydrogen, oxygen, and carbon monoxide under the same conditions as were observed with tubes of fused silica, but at a lower temp. It was assumed that the permeability of the walls of glass or fused silica vessels to gases is similar in character to the passage of gases through caoutchouc or animal membranes. C. Belloc regarded the phenomenon at high temp. as an effect of incipient devitrification. E. C. Mayer found a transparent vitreous quartz vessel to be impervious to hydrogen and oxygen at ordinary room temp., and atm. press., but was pervious to hydrogen at temp. higher than 330°, and at press. ranging between 26 cms. above and below atm. press. No leakage was detected with oxygen or nitrogen for press. below atm. Nitrogen did not escape until about 430°. In all cases, at constant temp., the leakage increased with an increase of press.—hydrogen leaked fastest, nitrogen slowest of the three gases in question. G. A. Williams found the permeability of silica glass for hydrogen becomes appreciable above 300°; and at high temp. it is proportional to the gas press., and is an exponential function of the temp. Observations on the diffusion of hydrogen were made by T. des Coudres, M. Bodenstein and F. Kranendieck, W. Watson, and H. Wüstner. The last-named found the coeff. of diffusion of hydrogen, in c.c. per sq. cm. per sec., to be:

	300°	400°	500°	600°	700°	800°	900°	1000°
Coeff. . .	0.0,73	0.0,16	0.0,21	0.0,24	0.0,24	0.0,42	0.0,76	0.0,103

with the hydrogen at 800–900 atm. press. He also made some observations on nitrogen and oxygen, but found the rate of diffusion to be very slow—particularly

in the case of oxygen. H. Wüstner also measured the absorption coeff., β , of hydrogen, and obtained:

	300°	400°	600°	700°	800°	900°	1000°
β	0.005483	0.005669	0.00819	0.009858	0.01092	0.01098	0.01029

so that the value at about 700° is the same as that of hydrogen in water at ordinary temp. H. von Wartenberg discussed the reduction of quartz by hydrogen above 1200°. R. S. Willow and H. T. George studied the absorption of gas in quartz discharge tubes; and A. F. Benton, the absorption of carbon dioxide, carbon monoxide, oxygen, and hydrogen by silica—*vide infra*, silica gels. E. E. Schumacher found that quartz is wetted by mercury when the adsorbed air is removed from the quartz.

The adsorption of water vapour by quartz has been studied by I. Ihmori,³ A. von Dobeneck, M. Guichard, W. Skey, H. E. Patten, R. E. Wilson and T. Fuwa, L. Vignon, and L. J. Briggs. The last-named found that quartz, like glass, is capable of condensing a water film upon its surface from an unsaturated atm. A part only of this film is liberated when the vap. press. is reduced to zero at 30°. The weight of the water film condensed on the surface of quartz at 30° in an atm. within one per cent. of saturation is 26.6 mgs. per sq. metre determined by drying at 110°. This corresponds to a calculated thickness of the water film of 2.66×10^{-11} cm., assuming the density of the film to be uniform and equal to unity. The results obtained with washed quartz do not support the conclusion that adsorption is due to the presence of soluble substances on the surface of the solid. H. E. Patten and F. E. Gallagher found that finely powdered quartz in an open dish over water adsorbed 0.23 per cent. of moisture at 23°; 0.11 per cent. at 43°; 0.05 at 62°; 0.03 at 80°; and 0.02 at 97°. A. von Dobeneck found that 100 grms. adsorbed 0.023 gm. of carbon dioxide at 0°, and virtually the same amount at 10°, 20°, and 30°. B. von Ammon found that quartz powder adsorbed 0.295 per cent. of ammonia at 20°. G. R. Paranjpe measured the effect of press. at -190° on the adsorption of hydrogen by quartz. The condensation of water vapour on the quartz appears to be due to the attraction of the solid for the mol. of the vapour, in accordance with the theory of J. W. Gibbs (1. '13, 22) as applied to the adsorption of dissolved substances. G. Schwalbe, and C. J. Parks have investigated the Pouillet effect with quartz and amorphous silica—*vide* 1. 9, 9.

In his *Meteorology*, Aristotle, 320 B.C., said that water is improved for drinking purposes by filtration through sand; and in his *Sylva sylvarum*, F. Bacon wrote of a method of obtaining fresh water from sea-water, by filtration through earth. S. Hales also mentioned that when sea-water is filtered through stone cisterns, the first pint that runs through will not taste of the salt, but the water afterwards collected will be as salt as usual. G. Matteucci also found that the first runnings of soln. of various salts, when filtered through sand, are free from salt. The phenomenon is here probably not altogether an adsorption effect, but is partly due to the more rapid passage of water as shown to be the case by S. Krakoff, and L. J. Briggs with soils. J. N. Mukherjee showed that silica adsorbs acids, although A. F. Joseph and J. S. Hancock could not confirm this. According to L. Vignon, quartz adsorbs the alkali hydroxides or carbonates, but not sodium chloride or magnesium chloride. Other chlorides, nitrates, and sulphates of the alkalies and silver nitrate are adsorbed from aq. soln. The adsorption with carbonates is rather less than with hydroxides; but the results with the alkalies are in some doubt because of the possible chemical action between soln. and solid. R. E. Wilson and T. Fuwa studied the humidity equilibria of silica. The adsorption of water vapour by the so-called amorphous silica is smaller the higher the temp. at which the silica has been calcined. E. Berl and W. Pfannmüller studied the effect of the flotation process on quartz.

Quartz is considered to be insoluble in water at ordinary temp. and press.

The solubility of silica in natural waters has been discussed in connection with the occurrence of silica—*vide supra* corrosion figures. It was also pointed out that J. H. Pott,⁴ A. Baumé, J. C. F. Meyer, and C. J. B. Karsten knew that the gelatinous precipitate from *liquor silicium* remains in soln. when treated with an excess of acid. Gelatinous silica, precipitated when silicon tetrafluoride is passed into water, was reported by J. N. von Fuchs to be slightly soluble in water—100 parts of water dissolving 0.013 part of silica. A. E. Delesse found an appreciable solubility at 160°. C. Struckmann found the water dissolved 0.021 part of silica which had been precipitated by carbon dioxide from a soln. of an alkali silicate; and O. Maschke obtained a soln. with 0.09 part of silica after many days' digestion. In these old measurements, the influence of alkalis derived from the solvent action of water on glass does not seem to have been excluded. E. Jordis showed that the solubility is influenced by the presence of acid or alkali in the water. The same remark applies to T. Graham's statement that 100 parts of water dissolve 0.02 part of silica precipitated from a one per cent. soln.; and 0.01 part of silica precipitated from a 5 per cent. soln. E. Ludwig found 100 parts of water dissolved 0.0037–0.0042 part of silica. A. E. Delesse showed that quartz is slightly soluble in water at 160°; and W. Skey stated that hydrated silica dissolves in water. H. Leitmeier found that 0.22 part of opal dissolves in 100 parts of boiling water, and that quartz and chalcedony are not so soluble. Observations on the solubility of silica in water have also been made by E. Manzella, J. Davy, J. Persoz, C. Viola, E. Nicholson, R. Biedermann, C. G. C. Bischof, A. M. Edwards, G. C. Wittstein and R. Pribram, A. Souchay, C. Mieneke, C. Winkler, C. Matignon and M. Marchal, P. Jannasch and O. Heidenreich, G. Gore, F. Meissner, W. Spring, G. B. Ercolani, M. Bellati and L. Finazzi, etc. S. Calderon found that 100 parts of water dissolve 0.01 part of silica, and that the solubility is increased in the presence of oxygen, carbon dioxide, nitric acid, sulphuric acid, and humic acids. H. W. F. Wackenroder found traces of silica in strong brines. Many other observations have been made. T. Graham thought that the solubility depended upon the degree of hydration, and that dehydrated silica is insoluble in water. This, however, is not the case. V. Lenher showed that the action of water on silica is that of a solvent, and this action is accelerated by the finer grinding of the silica, and by raising the temp. and the press. The water converts the silica into the gel form, which then passes into the sol condition. F. Seemann studied the solubility of silica in water and in soln. of ammonium carbonate, sodium chloride, and carbonic acid. R. Schwarz made a clear sol with 0.3 per cent. silica by evaporating a soln. of silicic acid in aq. ammonia slowly over conc. sulphuric acid.

V. Lenher and H. B. Merrill have shown (i) that gelatinous silica attains a state of equilibrium fairly quickly in water—about 24 hrs. suffice—and the solubility is 0.016 at 25° per 100 c.c. of water, and 0.0214 at 90°—the solubility is the same no matter how the gel is prepared; and (ii) that the solubility of ignited silica appears less than that of gelatinous silica because of the length of time required to saturate the soln. They say that in all probability the true solubilities of the ignited and gelatinous forms of silica are the same. The presence of carbon dioxide has no effect on the solubility of silica in water at 90°. The solubility is augmented by press. F. Pfaff found that at 18° and 290 atm. press., 100 parts of water dissolved 0.0213 part of silica. According to G. Spezia, the action of water on polished plates of quartz cut vertical and parallel to the chief axis in terms of the loss of weight in milligrams per sq. cm. of surface suffered in 30 days is illustrated by the results shown in Table VII. G. Spezia infers that press. plays but a subordinate rôle, and that temp. is the most important factor in determining the solubility of quartz in water. The solubility is greater in the direction of the chief axis than it is at right angles thereto.

It might be anticipated that **persilicates** analogous to the percarbonates could be prepared by evaporating silica gels with 30 per cent. **hydrogen dioxide**. A. Komarovsky⁵ did obtain a gelatinous residue which liberated chlorine from

TABLE VII.—EFFECT OF TEMPERATURE AND PRESSURE ON THE SOLUBILITY OF QUARTZ IN WATER.

hydrochloric acid, and iodine from hydriodic acid; it gave ozone when treated with conc. sulphuric acid, and decolorized soln. of potassium permanganate. Hence, it was inferred that either a **persilicic acid**, $\text{H}_2\text{SiO}_4 \cdot 1\frac{1}{2}\text{H}_2\text{O}$, or a **hydrogel of persilicic acid**, $\text{H}_2\text{SiO}_3 \cdot \text{H}_2\text{O}_2 \cdot \frac{1}{2}\text{H}_2\text{O}$, was formed. A. H. Erdenbrecher found that by triturating anhydrous or crystalline sodium metasilicate with 82 per cent. hydrogen dioxide and alcohol or ether, a porous mass containing up to 15 per cent. of active oxygen is obtained. It absorbs carbon dioxide and moisture from air, and evolves water and oxygen when heated.

According to H. Moissan,⁶ **fluorine** is the only halogen which attacks silica, and silicon tetrafluoride is formed even in the cold. If the silica be mixed with carbon, then, at a red heat, H. C. Oersted showed that **chlorine** furnishes silicon tetrachloride; and G. S. Sérullas, that **bromine**, gives silicon tetrabromide. H. Moissan found that **iodine pentafluoride** reacts vigorously with silica, forming silicon tetrafluoride. Quartz is scarcely affected by acids, excepting **hydrofluoric acid** which reacts with it, forming a volatile silicon fluoride. According to H. Rose, powdered quartz dissolves quietly in hydrofluoric acid; but silica of sp. gr. 2.2 dissolves with more violence. According to R. Schwarz, the amounts of the different modifications of silica dissolved by hydrofluoric acid during a period of 30 hrs., are as follows:

	Quartz.	Tridymite.	Cristobalite.	Quartz glass.
One per cent. acid	5.2	20.3	25.8	52.9 per cent.
Five per cent. acid	30.1	76.3	74.3	96.6 „

On the assumption that compounds are less attacked by hydrofluoric acid the more condensed the mol., J. B. Mackintosh assumed that the mol. of quartz is more condensed than that of opal because with dil. hydrofluoric acid, opal lost 77.28 per cent., while quartz lost only 1.56 per cent. The illustration is poor, because one is a hydrated and the other an anhydrous compound—*vide supra*, corrosion figures. According to J. Thomsen, the heat of soln. of hydrated silica in hydrofluoric acid approximates 48 Cals. per mol. of silica when the eq. of 12 mols. of hydrogen fluoride, HF, is used per mol. of silica; and 13.64 Cals. when 2.46 mols. of hydrofluoric acid are used. According to O. Mulert, the thermal value of the reaction with finely-powdered quartz in 20 per cent. hydrofluoric acid is 29.93 Cals. per mol. of silica, SiO_2 ; 32.14 Cals. per mol. of fused-silica, SiO_2 . R. Wietzel found that with 35 per cent. hydrofluoric acid, the heat of soln. per mol. of quartz-glass is 35.97 Cals.; with rock crystal, 33.65 Cals.; and with cristobalite, 35.37 Cals. Similarly, with fuming hydrofluoric acid, and quartz-glass, the heat of soln. is 38.83; rock-crystal, 36.48 Cals.; and chalcedony, 36.72 Cals. G. Tammann has also shown from measurements of the electrical conductivity that the soln. obtained in both cases is the same. Consequently, the heat of transformation of amorphous silica to crystalline quartz is about +2.21 Cals. The mol. ht. of soln. of quartz in hydrofluoric acid was found by P. C. Ray to be raised 2.17 Cals. by 15 hrs.' grinding;

this is taken to correspond with the conversion of 31.2 per cent. of quartz to the vitreous state. O. Mulert has shown that the heat of soln. of hydrated silica depends on the degree of hydration of the silica. It rises rapidly from 32.14 with amorphous anhydrous silica to 35.51 Cals. with silica with about 3 per cent. water, and then falls to about 33.5 Cals. with silica having about 10 per cent. of water; after which, the heat of soln. remains constant. The curve is illustrated in Fig. 48. The increase is supposed to indicate that the first 3 per cent. water absorbed by the silica is in a state of compression, and the energy compressing the water is liberated as heat; and when the silica is associated with more water, the compression diminishes and consequently less heat is liberated.

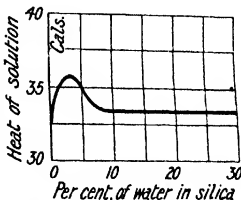

FIG. 48.—Heat of Solution of Hydrated Silica in Hydrofluoric Acid.

G. Gore found that liquid hydrogen chloride has no action on silica. According to M. Wunder and A. Suleimann, when gelatinous silica is digested for 2 hrs. on a water-bath with 1 : 2 hydrochloric acid, 0.12 grm. of silica per litre passes into soln., and 0.03 grm. of silica per litre after 12 hrs.' digestion at 16°; with 1 : 1 acid, the results were respectively 0.14 and 0.03 grm. of silica per litre; and with 2 : 1 acid, 0.331 and 0.05 grm. per litre. C. Struckmann, O. Masche, and G. C. Wittstein made observations on this subject, *vide supra*. V. Lenher and H. B. Merrill found the solubility in grms. per 50 c.c. at 90° to be:

Per cent. HCl	0	2.0	5.4	7.8	10.0	15.4	18.7
SiO ₂	0.0212	0.0198	0.0152	0.0114	0.0091	0.0046	0.0028

and at 25°:

Per cent. HCl	0	3.0	6.4	12.0	18.9	25.1	34.9
SiO ₂	0.0081	0.00665	0.0044	0.0023	0.0008	0.0006	0.0004

The results are plotted in Fig. 49. J. M. van Bemmelen found that 0.81, 2.27, and

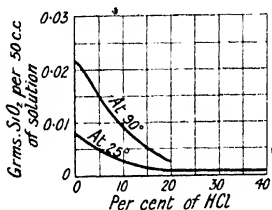

FIG. 49.—Solubility of Silica in Hydrochloric Acid per 50 c.c. of Solution.

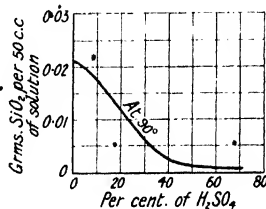

FIG. 50.—Solubility of Silica in Sulphuric Acid per 50 c.c. of Solution.

4.2 mgrms. eq. of hydrochloric acid were absorbed by 10 grms. of gelatinous silica dried at 100° from 100 c.c. of soln., containing respectively 20, 50, and 100 mgrms. eq. He assumed that the water in the silica was replaced by acid. C. J. B. Karsten discussed the action of acids on silica; and G. C. Wittstein, of aqua regia. E. Jordis and E. H. Kanter assumed from conductivity measurements that when hydrochloric acid is added to colloidal silica, combination occurs. C. J. B. Karsten also assumed that a compound of silica and hydrochloric acid can be formed. This was supported by F. Mylius and E. Groschuff. J. Meyer inferred that the amount of hydrogen chloride retained by silica after 4 hrs.' ignition at 1000° is inappreciable. T. Bauer has referred to the difficulty of getting rid of the last traces of hydrochloric acid from silica.

According to F. Koref,⁷ and A. Gautier, silica at 800°–1100° is attacked by the

vapour of **sulphur**, **hydrogen sulphide** or of **carbon disulphide**, forming silicon sulphide (*q.v.*). R. D. Hall said that **sulphur chloride**, S_2Cl_2 , has no action on heated silica; F. Bourion found that a mixture of chlorine and the vapour of sulphur chloride has virtually no action on precipitated silica at 575° ; and at a dull red heat, C. Matignon and F. Bourion found that silicon tetrachloride is readily formed. W. B. Schmidt found that **sulphurous acid** has but a slight action on silica. According to M. Wunder and A. Suleimann, dil. sulphuric acid (1:2 dissolves 0.02 grm. and 0.04 grm. of silica per litre when digested on a water-bath and at 18° respectively. L. Wöhler and co-workers studied the action of silica in the contact process for sulphuric acid. V. Lenher and H. B. Merrill gave for the solubility of gelatinous silica in sulphuric acid in grams per 50 c.c. at 90° :

Per cent. H_2SO_4 . . .	0	3.9	7.3	11.5	25.4	55.6	71.0
SiO_2 . . .	0.0214	0.0211	0.0184	0.0144	0.0058	0.0005	0.0004

The results are plotted in Fig. 50. Observations were also made by S. Calderon. J. M. van Bemmelen found that 1.1, 2.17, and 4.0 mgrms. eq. of sulphuric acid were absorbed by 10 grms. of gelatinous silica dried at 100° from 100 c.c. of soln. containing respectively 20, 50, and 100 mgrms. eq. of sulphuric acid; the acid was assumed to replace the water in the hydrated silica, forming a kind of combination.

H. Funk⁸ studied the action of **nitrogen** on silica during which a nitride (*q.v.*) is formed. C. J. B. Karsten found that aq. **ammonia** readily dissolves freshly precipitated silicic acid, but a soln. of ammonium carbonate dissolves very little. G. C. Wittstein also found that calcined silica is soluble in aq. ammonia, and if a soln. of water-glass, mixed with an excess of hydrochloric acid, be treated with ammonia, the flecks first formed are dissolved when more ammonia is added. According to R. Pribram, 100 parts of 9.75 per cent. aq. ammonia dissolve 0.714 part of gelatinous silicic acid, 0.303 part of dried silicic acid, 0.377 part of dehydrated silicic acid, and 0.017 part of quartz. A. Souchay found 100 parts of aq. ammonia dissolve 0.382 part of silica dried at 100° , 0.357 part of calcined silica, and 0.00827 part of quartz. H. Kühn, and J. Persoz also observed the ready solubility of silicic acid in aq. ammonia. The phenomenon is complicated by the action of alkalis derived from the glass containing vessel. C. Struckmann found that 100 parts of 19.2 per cent. aq. ammonia dissolved 0.071 part of silica, and 100 parts of a 1.6 per cent. soln., 0.0086 part of silica. Observations were also made by W. Skey, A. M. Edwards, etc. L. J. Briggs found that if the conc. of an aq. soln. of ammonia after absorption be represented by C mols per litre, and the total adsorption by 100 grms. of quartz powder of surface area 100,000 sq. cms. be represented by A mols per litre, then:

C . . .	0.0008	0.0032	0.0102	0.0344	0.1052
A . . .	0.55×10^{-4}	0.74×10^{-4}	1.04×10^{-4}	2.94×10^{-4}	7.68×10^{-4}

According to R. Schwarz, the peptizing action of the ammonia makes itself noticeable at a conc. of 0.001N; for 3N-ammonia the amount of dissolved silicic acid lies between 63.4 per cent. and 67.4 per cent. for different specimens of the gel. Between the conc. 3N- and 6N-ammonia the solubility does not change materially, and from this conc. upwards the solubility decreases.

H. Rose observed that silica may be completely volatilized as silicon tetra-fluoride when heated with two or three times its weight of **ammonium fluoride**—J. B. Mackintosh, K. Daniel, F. Leydolt, and F. von Kobell have made observations on this subject. When heated with **ammonium chloride**, artificial silica becomes denser and less readily attacked by reagents. L. J. Briggs found that if the conc. of an aq. soln. of **ammonium carbonate** after adsorption be denoted by C mols per litre, and the total adsorption by 100 grms. of quartz of surface area 100,000 sq. cms. be represented by A mols per litre, then:

C . . .	0.0022	0.0063	0.0208	0.063
A . . .	0.09×10^{-4}	0.45×10^{-4}	0.45×10^{-4}	1.8×10^{-4}

A. W. Titherley found that when a mixture of silica and an **alkali amide** is heated between 300° and 400°, ammonia is evolved, and at still higher temp., ammonia, hydrogen, and nitrogen are given off. The residue contained the alkali silicate and silicon nitride. When gelatinous silica is digested with dil. **nitric acid** (1 : 2 ; 1 : 1 ; and 2 : 1) on a water-bath for 2 hrs., respectively 0.10, 0.08, and 0.04 grm. of silica per litre passes into soln., and when digested for 12 hrs. at 18°, respectively 0.02, 0.03, and 0.03 grm. of silica per litre dissolves. S. Calderon made some observations on this subject. J. M. van Bemmelen found that 0.86, 2.17, and 1.0 mgrms. eq. of nitric acid were adsorbed by 10 grms. of gelatinous silica dried at 100° from 100 c.c. of soln. containing respectively 20, 50, and 100 mgrm. eq. of nitric acid. The water of the silica is replaced by nitric acid which forms a kind of compound with the silica. G. C. Wittstein also tested the solubility of silica in *aqua regia*.

Silica has in a marked degree the power of forming complex acids. The silicophosphates, silicotungstates, silicomolybdates, silicovanadates, silicotitanates, and the silicostannates can be cited in illustration. A. V. Bleininger and P. Teetor⁹ obtained no evidence of the formation of a compound in their study of the glasses obtained by fusing mixtures of silica and boric oxide. The action of soln. of phosphoric acid, of fused sodium phosphate, of phosphorus pentoxide, and fused metaphosphoric acid is discussed in connection with the silicon phosphates, *vide infra*. A. Daubrée found that **phosphorus trichloride** converts silica into silicon tetrachloride ; R. Weber obtained a similar result with phosphorus pentachloride ; and A. Simon showed that **phosphorus trifluoride** yields silicon tetrafluoride. The action of **carbon** and of **calcium carbide** on silica has been discussed in connection with silicon carbide. Reports as to whether the presence of **carbon dioxide** in soln. in water exercises any influence on the solubility of silica are discordant. C. Struckmann¹⁰ said that the solubility is diminished ; V. Lenher and H. B. Merrill said that at 90°, the effect of carbon dioxide on the solubility of silica in water is *nil*. F. Seemann, O. Masche, and S. Calderon made some observations on the subject. C. Matignon and G. Marchal examined the corrosive action of water on quartz in the presence of carbon dioxide under 10 atm. press. during 3 years' action. S. Medsforth studied the action of silica on nickel as a catalyst in the reduction of carbon monoxide and dioxide by hydrogen. A. Finckley and W. H. Harby found that colloidal silica exercises no influence on the solubility of carbon dioxide in water. A. Simon found that **carbon tetrafluoride** converts silica into silicon tetrafluoride ; and E. Demarçay said that **carbon tetrachloride** slowly converts red-hot silica into silicon tetrachloride, and H. E. Quantin found that silicates also yield silicon tetrachloride, and this the more readily the greater the proportion of combined alumina in the silicate. *Au contraire*, L. Meyer, and P. Camboulives said that silica is not attacked when heated in a stream of the vap. of carbon tetrachloride, and the latter applied the fact to the analysis of complex minerals. For instance, a separation of free and combined silica in bauxite can be effected in this way, since aluminium silicate is transformed into the chlorides of aluminium and silicon, whilst uncombined silica is not attacked. P. Sabatier and A. Mailhe found that silica acts catalytically on the decomposition of formic acid into carbon dioxide, water, and formaldehyde ; and J. B. Senderens, and A. Kling, that silica acts catalytically on the thermal decomposition of alcohols. D. Konowaloff found silica acts catalytically on the decomposition of amyl acetate vapour ; C. H. Milligan and E. E. Reid, on acetic acid, and ethyl alcohol vap. ; and M. Bodenstein and F. Ohlmer, on the oxidation of carbon monoxide. E. Berl and W. Pfannmüller, W. Suida, E. Dittler, and L. Pelet-Jolivet studied the action of silica, quartz, etc., on organic dye-stuffs. The basic dyes are adsorbed particularly when the grain-size is approximately 10 μ . It has been affirmed by F. Verdeil and E. Risler¹¹ and denied by A. Petzholdt that silica is soluble in a soln. of sugar. J. Weissberg found that calcined silica is much less soluble in saccharine soln. than partially dried silica.

J. J. Berzelius¹² found that at a white-heat silica and **potassium** form potassium silicate and silicide; and that a mixture of silica and carbon, in the presence of **copper, silver, or iron**, at a white heat, forms carbon monoxide and a silicide of the metal. J. S. Stas also noted that silica is attacked and reduced by molten silver or silver vap. G. A. Faurie made some observations on this subject. J. B. J. D. Bous-singault also found that when a mixture of silica and carbon with **platinum, pal-ladium, ruthenium, or iridium** is heated, a metal silicide is formed. R. Bunsen and A. Matthiessen, and H. Moissan found that **calcium** and **strontium** reduce silica at a red-heat. A. Burger also studied the action of calcium. F. Krafft found that these metals, freed from the oxide, can be distilled in quartz vessels; and A. Schuller showed that under diminished press. in quartz vessels, silver can be volatilized at a temp. below its m.p.; a deposit of lead was observed when com-mercial silver was employed; copper can be sublimed when heated in quartz vessels; **gold** volatilizes very slowly at about its m.p.; **tin** can be distilled somewhat more easily than gold. For the action of the various **metals** on silica, *vide* the silicides.

L. J. Briggs¹³ measured the adsorption A by 100 grms. of surface area 100,000 sq. cm. of powdered quartz in mols, when the conc. of the soln. after adsorption was C mols per litre, and found with **sodium hydroxide**:

C . . .	0.0007	0.0026	0.0078	0.028	0.0866
A . . .	0.42×10^{-4}	0.79×10^{-4}	1.48×10^{-4}	3.45×10^{-4}	8.10×10^{-4}

and with **potassium hydroxide**:

C . . .	0.0009	0.0021	0.0063	0.0235
A . . .	0.33×10^{-4}	0.91×10^{-4}	1.63×10^{-4}	3.3×10^{-4}

The adsorption curves for ammonium and the alkali hydroxides are similar in form. The amount adsorbed is not directly proportional to the conc., but is relatively greater in very dil. soln., so that the ratio of the amount adsorbed to the conc. of the soln. decreases as the conc. is increased. The apparent adsorption of potassium hydroxide by quartz when in equilibrium with a tenth-normal soln. is 1.66×10^{-5} gm. mols. per sq. metre, which is eq. to about 0.6 mg. of potassium hydroxide per square metre of surface. The adsorption of potassium hydroxide by a fine quartz sand from a tenth-normal soln. amounts to only 1 per cent. of the salt contained in a vol. of soln. sufficient to saturate the sand. R. E. Hall and co-workers discussed the solubility of quartz in hot alkaline waters. For the action of fused alkali hydroxides, *vide infra*, alkali silicates.

According to C. F. Rammelsberg,¹⁴ quartz is but slightly attacked by a soln. of potassium or sodium hydroxide; hydrated silica is fairly soluble in this men-struum; while the opals, and chalcedonies are readily attacked. Thus, H. Leitmeier found that with different samples of chalcedony, a variety of chalcedony (or opal), called *cacholong*, and quartz, the attack by a 2 per cent. soln. of potash-lye at 85° for 5 hrs. was related with the amount of water associated with the chalcedony, as indicated in Table VIII. Many other observations on this subject have been

TABLE VIII.—ACTION OF POTASSIUM HYDROXIDE ON QUARTZ.

Variety of silica.	Sp. gr.	Water. Per cent.	Quartz dissolved. Per cent.
Quartz (Rauris)	2.613	0.22	7.23
Chalcedony (Farøe)	2.591	1.02	42.30
Cacholong (Farøe)	2.370	1.35	54.49
Chalcedony (Weitendorf)	2.608	1.50	76.02

made—*vide supra*, corrosion figures. It is not possible to estimate accurately the proportion of opal and quartz, in a sample of chalcedony, flint or chert, from the

amount dissolved in alkali-lye in a given time, because fine-grained quartz is attacked at the same time. The attack by alkali-lye depends on the conc. of the soln., the grain-size of the mineral, the temp., and time of action. Contradictory results have been published for the effect of, say, 10 per cent. soln. of alkali-lye on quartz because the effect of the size of grain has been overlooked. J. W. Mellor¹⁵ showed that with a sample of clear rock crystal, and a sample of flint from Dieppe, with a 15 per cent. soln. of potassium hydroxide:

Average diameter of grain	0.165 mm.	0.032 mm.
Rock crystal dissolved	0.96	6.40 per cent.
Flint dissolved	2.52	12.10 "

G. Lunge and M. Schochor-Tscherny found with a sample of powdered quartz after 2 hrs.' action, the percentage amount of quartz dissolved was:

	Potassium hydroxide soln.		Sodium hydroxide soln.	
	10 per cent.	5 per cent.	10 per cent.	5 per cent.
Quartz dissolved	21.36	16.84	19.80	16.20

In 32 hrs. all was dissolved by a 15 per cent. soln. of potash-lye, and soda-lye required 2 hrs. longer under similar conditions. F. Mylius and F. Förster confirmed the conclusion that the action of a soln. of potassium hydroxide on silica is quicker than that of sodium hydroxide.

J. A. Hedvall¹⁶ found precipitated silica was the only form of silica which reacted appreciably with **calcium oxide** at 1000°, though silica glass acts slightly; the formation of a silicate occurred at 1400° with cristobalite, while quartz did not act so rapidly. The formation of a silicate with **barium oxide** was appreciable with precipitated silica at 900°, and increased slowly with rise of temp. No sign of reaction was observed with **magnesium oxide** at 900°. According to E. Joridis and E. H. Kanter, aq. soln. of the **hydroxides of the alkaline earths** react slowly with finely divided quartz, forming the corresponding hydrated silicates; the systems were not in equilibrium after standing 16 days. The reaction is much faster with lime than with baryta or strontia—*vide* calcium silicates. According to K. Hebbeler, if kieselsguhr be shaken up with water; allowed to settle; the clear water decanted off and replaced by lime-water; and the lime-water be renewed daily 14 times, the sediment expands to nearly three times its vol. in water. No calcium silicate is formed, but calcium hydroxide is deposited about the kieselsguhr, and can be removed by repeated extraction with water. The action of lime-water on silica was studied by J. W. Döbereiner, A. Petzholdt, etc.

In making the so-called *sand-lime bricks*—used for building purposes—sand is mixed with milk of lime; pressed into the desired shape; rapidly heated to 80° or 100°; and then heated under a press. of from 5–10 atm. for 8 hrs. in an autoclave. The lime and quartz are thus bound together by a product which F. Rinne believed is analogous with *plombierite*, $\text{CaSiO}_3 \cdot 2\text{H}_2\text{O}$, found by A. Daubrée in the deposits from the thermal springs of Plombières. M. Glascnapp found that in any case, from 3–10 per cent. of the silica becomes soluble in acid, and this the more the higher the press. in the autoclave. The action of lime on silica in mortars has been studied by A. Petzholdt.

L. J. Briggs¹⁷ showed that the general behaviour of soln. of the alkali carbonates resembles that of soln. of the alkali hydroxides, but adsorption is more marked with the hydroxides than with the carbonates. Using *A* and *C* with the same meanings as before, with **sodium carbonate**:

<i>A</i>	0.0004	0.0012	0.0032	0.0106	0.0356	0.108
<i>C</i> × 10 ⁴	0.06	0.18	0.97	1.13	1.65	1.95

and with **potassium carbonate**:

<i>A</i>	0.0029	0.0093	0.0302	0.0910
<i>C</i> × 10 ⁴	0.45	0.76	1.65	2.4

There have been differences of opinion as to the action of the alkali carbonates, but

here again the result is largely due to differences in the grain size of the powders submitted to the reagent. G. Lunge and M. Schochor-Tscherny found with a given sample after 2 hrs.' action :

	Potassium carbonate soln.			Sodium carbonate soln.		
	15 per cent.	10 per cent.	5 per cent.	15 per cent.	10 per cent.	5 per cent.
Quartz dissolved	9.10	6.96	6.36	10.92	8.52	3.10

With coarser powder the action is very considerably reduced. R. Schwarz found that with powdered quartz and tridymite, of similar grain size, half an hour's boiling with a 5 per cent. sodium carbonate soln. dissolved 2.11 per cent. of quartz, and 2.77 per cent. of tridymite—*vide supra*, corrosion figures. The action of soln. of alkali carbonates on silica has been studied by G. Forchhammer, F. Pfaff, L. Doveri, T. Scheerer, O. Maschke, etc. J. W. Cobb found that mixtures of silica and sodium carbonate begin to react at about 700°, nearly 150° below the m.p. of the more fusible constituent of the mixture. For the action of fused alkali carbonates, *vide infra*, alkali silicates.

J. W. Cobb found that **sodium sulphate** begins to react with silica between 1120° and 1130°. J. M. van Bemmelen¹⁸ investigated the adsorption of soln. of salts by silica, 10 grms. of gelatinous silica dried at 100° in contact with a soln. of 20, 50, and 100 mgrms. eq. of salt per 100 c.c. of soln., adsorbed respectively 1.0, 2.5, and 4.56 mgrms. eq. of **potassium sulphate**; and with soln. containing 20 and 50 mgrms. eq. of salt per 100 c.c., respectively 0.9 and 2.14 mgrms. eq. of **potassium nitrate**, and 0.85 and 2.16 of **potassium chloride** were adsorbed. The quantity adsorbed is roughly proportional to the conc. of the soln., but with the more conc. soln. the amount adsorbed is less than corresponds with this relation. The 10 grms. of silica employed by J. M. van Bemmelen contained the eq. of 5.5 c.c. of water, and he noted that the amount of salt adsorbed corresponds to a bodily removal of from 4–4.5 c.c. of the soln. This suggested that when the silica was put into a soln., the water it contained was replaced by an equal vol. of the soln. G. C. Schmidt obtained results with potassium chloride in agreement with those of J. M. van Bemmelen, and he concluded that dissolved substances are taken up by precipitated silica mainly in the form of solid soln. rather than through adsorption processes. A. Schuller found that **sodium chloride** may be sublimed under reduced press. in quartz vessels. F. Seemann, J. W. Mellor, V. Lenher and E. Truog, and A. F. Joseph and J. S. Hancock studied the effect of sodium chloride on the solubility of silica. J. W. Mellor suggested that the solubility of silica in soln. of sodium chloride is due to the formation of a sodium silicate. This suggestion was confirmed by A. F. Joseph and J. S. Hancock. H. C. McNeil noted the solubility of silica in fused **barium chloride**.

G. Spezia¹⁹ found that a 5 per cent. soln. of **borax** dissolved about 74 mgrms. per sq. cm. in 4 days from a polished plate of quartz between 290° and 315° under a press. of 76–106 atm.; but virtually none was dissolved in 20 days between 12° and 16° and 6000 atm. press. The action of borax soln. was also investigated by E. Schweizer, and L. Doveri—*vide supra*, corrosion figures. G. Spezia also found analogous results with a soln. of **sodium silicate**, under a press. of 6000 atm.—there was virtually no action between 18° and 20°, and an appreciable action between 165° and 160°—*vide supra*, corrosion figures. C. Doelter²⁰ has studied the solubility of quartz in certain **fused silicates**—sanidine, albite, and labradorite—and C. Friedel found that fused **potassium bisulphate** slowly attacks quartz, and produces corrosion figures which change their symmetry at a temp. corresponding with the optical mutations at 570°. P. Hautefeuille studied the solubility of silica in fused **sodium tungstate**—*vide supra*.

A. Schuller²¹ found that **silver sulphide** and **lead sulphide** are readily sublimed in quartz vessels under reduced press. L. Troost and P. Hautefeuille found that **aluminium chloride** and **zirconium chloride** have no action on heated silica. According to W. Skey, finely divided, feebly calcined silica decomposes aq. soln.

of **chromic, cupric, or ferric acetate**, and precipitates the hydroxide. Quartz also decomposes ferric acetate soln.

In 1664, J. R. Glauber, in his *Novum lumen chymicum* (Amstelodami, 1664), noted the reaction between sand and any alkali salt; and in 1809, J. L. Gay Lussac and L. J. Thénard²² observed that silica and **sodium chloride** react to form hydrogen chloride and sodium silicate; but in the absence of moisture, no reaction occurs even at a white heat. C. F. Schönbein made a similar observation. As previously indicated—2, 20, 13—sodium chloride is readily dissociated by steam at an elevated temp. F. de Balande and M. Prud'homme, and H. Schulze noted that chlorine is also formed with dry oxygen; and A. Gorgen observed that there is a reaction between heated sodium chloride and silica in dry or moist air. The reaction has been further discussed by R. A. Tilghman, W. Gossage, R. Lieber, A. Blanc and T. P. Bazille, T. Williams, G. Fritzsche, H. Grüneberg and J. Vörster, H. H. Lake, C. F. Claus, and A. Ungerer—2, 20, 28. According to F. H. Clews and H. V. Thompson, silica and sodium chloride when strongly heated interact to give, in dry air, sodium silicate and chlorine; in moist air, sodium silicate, hydrochloric acid, and a small quantity of chlorine; in moist nitrogen, sodium silicate and hydrochloric acid. The lower temp. limit of the reaction is about 600°, and the extent of the reaction is still very small at 1000°. A rise in temp. and the presence of moisture increase the velocity of the reaction. The results obtained by varying the proportions of sodium chloride and silica indicate that the area of contact is more important than the composition of the mixture, unless the proportion of salt falls much below 50 per cent. H. V. Thompson, W. J. Rees, L. M. Wilson, and A. E. Findley, have studied the reaction from the point of view of the resistance of silica bricks to the fumes of alkali and ammonium chlorides when salty coals are employed in coke ovens, and vertical gas-retorts. The temp. in the former case is comparatively low, but the action is prolonged month after month, so that drastic changes can be produced under conditions where the effects are inappreciable in ordinary laboratory experiments. According to F. H. Clews and H. V. Thompson, quartz is more reactive than precipitated silica or tridymite at 1000°. This does not agree with observations made in other directions. W. Loewenstein measured the solubility of silica in molten **calcium chloride**, and found:

	800°	850°	900°	950°
Per cent. SiO ₂	2.5	3.8	5.4	7.6

and he calculated the heat of soln. to be—19,225. There is a reaction, $\text{SiO}_2 + \text{CaCl}_2 = \text{CaSiO}_3 + \text{Cl}_2$. G. Marchal found that silica begins to react with **calcium sulphate** at 870°.

§ 20. The Uses of Silica

* As previously indicated, quartz was fused in the flame of the oxyhydrogen blowpipe by R. Hare,¹ in 1802; and later by E. D. Clarke, and others—*vide supra*, the melting of silica. In 1839, A. Gaudin noticed that the glass obtained by melting quartz does not exhibit double refraction, and he also showed that the molten quartz can be worked like glass, and he made threads of fused quartz over a metre long. A. Gautier exhibited spiral threads of fused quartz in 1878. C. Despretz, and C. A. Parsons fused silica by passing an electric current through a carbon rod embedded in sand, and thus obtained a hard fused silica tube. No industrial use for quartz-glass had been found until C. V. Boys, in 1889, showed that the low coeff. of thermal expansion, and the toughness of quartz-glass fibres rendered it a valuable means of suspending the magnets and mirrors of galvanometers. In 1901, R. S. Hutton, and W. A. Shenstone prepared quartz-glass, and laid the foundation of an industry for the manufacture of vessels of vitreous quartz. Various names are applied to the vitrified quartz—thus, *quartz-glass*, *vitreous-silica*, *fused quartz*, *silica-glass*, *vitrosil*, etc. Vessels made of this material—tubes, flasks, retorts, dishes, etc.—can now be used for various apparatus required in laboratory or factory.

The manufacture of vessels of quartz-glass offers many difficulties. For example, the elimination of air entangled between the grains during fusion is not easy. In W. C. Heraeus' ² process the quartz is first heated to nearly 600° so as to shatter it up into small pieces. The fragments are then fused in crucibles—made from iridium, or a mixture of alumina and zirconia. Small quantities of the material can be worked in the oxyhydrogen flame like glass in the ordinary gas blowpipe. In another type of silica ware, an electrode of the desired shape is embedded in good quartz sand, and heated electrically. The material near the electrode is sintered together; that furthest away is not fused. The electrode is removed when the furnace cools, and a vessel with an internal shape like the electrode remains. The vessel can be dressed by grinding, etc., and the inner surface can be vitrified by the oxyhydrogen blowpipe. This ware is translucent or opaque, and permeated with numerous air-bubbles. In order to eliminate air-bubbles the British Thomson-Houston Co. fuses the quartz in vacuo, and compresses the plastic mass.

The trade name for a product obtained by fusing silica with 0.1–2 per cent. of zirconia is called *Z-siloxide*; and if titania is used, *T-siloxide*. F. Thomas ³ states that these products are less liable to devitrification than vitrosil, or quartz-glass, but A. C. Michie denies this, and claims that these additions make quartz-glass more liable to devitrification. F. Thomas also claims that the siloxides resist attack by alkalis and molten metals better than quartz-glass.

In virtue of its very small coeff. of thermal expansion, vessels made from quartz-glass can be rapidly cooled or rapidly heated without cracking; for instance, a flask made of quartz-glass can be heated red-hot in the blowpipe, and immediately plunged into cold water without fracture—ordinary glass under the same conditions would shatter into fragments. The softening temp. approaches 1600°.

Although long pyrometer tubes, if not adequately supported, will bend if heated to 1200°. This might be anticipated since quartz-glass—like ordinary glass—is an under-cooled fluid, which, at ordinary temp., is viscid enough to be rigid and hard, but which, on heating, becomes less and less viscid. Lord Rayleigh detected evidence of a crystalline structure in a specimen of quartz-glass. The absence of a definite m.p. also explains the discrepancies between the different reports of the m.p. of quartz-glass.⁴ Quartz-glass has no real melting temp. If heated for long periods—say at 1200°—quartz-glass devitrifies owing to the formation of crystals of cristobalite or tridymite (Fig. 26). The glass then becomes opaque, brittle, and doubly-refracting. Vessels made of quartz-glass also cease to be gas-tight.⁵ The crystallization introduces tremendous strains in the body owing to the contraction which takes place about each centre of crystallization. The sp. gr. of the opalescent or devitrified glass approaches 2.3. The properties of quartz-glass—physical and chemical—have been described in connection with those of silicon dioxide.

Sandstone and quartzite are used for building stones, grinding stones, whetstones, runners and pavers for grinding pans, etc. In making firebricks, ground sandstone, ganister, quartzite, or a similar rock is intimately mixed with a little milk of lime so as to add a total of say 2 per cent. of calcium oxide. The mixture is moulded into bricks, and fired to 1300°–1500°. The resulting *ganister bricks*, *silica bricks*, or *Dinas bricks* are highly refractory—in some cases withstanding furnace temp. approximately 1700°. This is higher than the fusion temp. of the bricks. The bricks maintain their form because the high temp. affects only the face of the brick; the bricks are cooler a short distance from the face. Instead of lime, other binding agents are used—e.g. clay, basic slag, etc. The siliceous rock may be associated with enough clay to render further additions unnecessary. If the silica bricks are inadequately fired, they may expand inconveniently in use; this is due to the slow conversion of quartz into forms of silica with a low sp. gr. A little expansion is not a bad thing, for it may help to keep the joints of flues, etc., tight. Quartose sands, ground flint, ground quartzites, and the like are also used in the manufacture of soaps, white paints, polishing powders, soluble glass, cements, enamels, glazes, glass, and in the ceramic industries.

Many of the gem varieties of quartz are shaped into ornaments and gem-stones. Diatomaceous earth or kieselguhr—wrongly called *infusorial earth*—is used as a polishing powder, and in the manufacture of soaps as a substitute for pumicestone. The absorbent properties of kieselguhr are utilized for the preparation of solid disinfectants by the absorption of liquid antiseptics for the dry dressing of wounds; and for the absorption of bromine, sulphuric acid, and nitroglycerol. Kieselguhr soaked in nitroglycerol is called *dynamite*. The poor heat-conducting qualities of diatomite make it a valuable insulating and fireproof packing for heating furnaces, powder magazines on board ships, cold storage rooms, etc. Diatomite bricks are also very light and porous, and are poor conductors of sound. K. Hebbeler⁶ has discussed the increase in vol. which occurs in sedimented kieselguhr when the water is replaced by lime-water—*vide supra*. Silica was found by C. H. Milligan and co-workers⁷ to be a better catalyst than either thoria or titania for esterification reactions in the vapour phase. W. A. Patrick described the preparation of silica hydrogels as catalysts when fortified with various metal colloids as promoters; and J. N. Pearce and A. M. Alvarado, the effect of silica as a catalyst in esterification.

§ 21. Silicic Acids or Colloidal Silica

Colloids and crystalloids appear to belong to different worlds of matter, and give occasion to a corresponding division of chemical science. The distinction between these kinds of matter is that subsisting between the material of a mineral and the material of an organized mass.—T. GRAHAM.

The natural forms of amorphous hydrated silica are classed as opals—*vide supra*, the occurrence of silica. The gelatinous masses obtained by treating with acids soluble alkali silicates, zeolites, and many other natural silicates, are sometimes called silicic acids. The history has been discussed by P. Walden,¹ and R. Frühling. According to L. Doveri,² when hydrochloric acid is added drop by drop to a soln. of an alkali silicate, the greater part of the contained silica is precipitated as hydrate, but if the same quantity of acid be added at once, very little of the silica is deposited. T. Graham prepared the **hydrogel of silicic acid** by pouring conc. hydrochloric acid into a conc. soln. of sodium silicate containing about 25 per cent. of silica, SiO₂, and washing the precipitated silica free from soluble salts. H. A. Fells and J. B. Firth said that the removal of the sodium chloride before or after heating makes no material difference to the adsorption capacity of silica gel for water. The hydrate was made by F. C. Kuhlmann, F. Ullik, P. Rohland, E. Jordis, W. Kühne, J. M. van Bemmelen, F. Bayer, W. A. Patrick, P. G. Somerville and E. C. Williams, F. X. Govers, B. Kühn, J. H. Frydlander, etc. E. Jordis said that the precipitate is finer and more flocculent the greater the dilution of the soln., and that in this state it can be readily washed. The following process may be employed:

Dissolve 50 grms. of commercial precipitated silica in a soln. of 12 grms. of sodium hydroxide and 50 c.c. of water. Dil. the soln. to 200 c.c. and heat the liquid to about 100°; add hydrochloric acid. Wash the precipitate on a Büchner's funnel with hot water. Again stir up the hydrogel with hot water, and wash on the funnel until free from chlorides. Sodium salts are more easily washed from the silica than potassium salts.

J. J. Berzelius obtained the gel by treating silicon tetrafluoride with water. C. Langlois used silicon tetrachloride; J. J. Ebelmen, ethyl orthosilicate; E. Grimaux, methyl silicate. B. Kempe considered the hydrolysis of ethyl ester to be too slow a process. A. C. Becquerel also observed the formation of gelatinous silica about the positive pole when a soln. of potassium silicate was electrolyzed; and M. Kröger found that by the electrolysis of a 1.5 per cent. soln. of water-glass between a mercury cathode and a platinum anode a clear hydrosol of silicic acid which did not gelatinize for 4 weeks collected in the anode compartment; the sol from a 6 per cent. soln. of water-glass gelatinized immediately it was formed; and with a 30 per cent. soln., silica was deposited on the anode. J. F. Spencer and K. Proud made orthosilicic acid by the electrolysis of a 50 per cent. soln. of sodium silicate in a divided cell with a heavy anode current-density. A platinum dish served as cathode, and a coil of platinum wire in a porous pot served as anode. The glass-like deposit on the platinum wire was entirely insoluble in water, and stable in air. H. C. A. Holleman³ described the manufacture of silica gel for use as an adsorbent.

By adding 100 c.c. of a mixture of equal parts of conc. hydrochloric acid and water, slowly, drop by drop, and with constant stirring, to a soln. of water-glass, or to a soln. of 60 grms. of sodium metasilicate in 200 c.c. of water, **silica hydrosol or soluble silica** is formed. The silica hydrosol remains in soln. along with the excess of hydrochloric acid and the sodium chloride formed in the reaction: $\text{Na}_2\text{SiO}_3 + 2\text{HCl} \rightleftharpoons \text{H}_2\text{SiO}_3 + 2\text{NaCl}$. The hydrochloric acid and the sodium chloride can be separated from the hydrosol by dialysis (Fig. 51). T. Graham found that after four days' dialysis, the liquid in the dialyzer was no longer rendered turbid by a soln. of silver nitrate. E. Jordis, on the contrary, maintained that the chlorine is a constitutive part of the silica in soln., but R. Zsigmondy and R. Heyer confirmed T. Graham's conclusion that the chlorine can be all removed by dialysis; and, in order to ensure rapid dialysis, the dialyzer illustrated in Fig. 51 can be used in place of the simpler form used by T. Graham. In the improved apparatus a current of water is kept circulating about the outside of the dialyzing membrane. The dialyzing surface is also relatively great, so that the operation is much quicker than before. The liquid in the dialyzer is protected from dust by a plug of cotton wool. Acetic acid (E. M. Plessy), oxalic acid (E. Monier), and sulphuric acid (S. Meunier) have been used in place of hydrochloric acid. Hydrosols of silica have been obtained in many other ways. The dialysis of colloidal silica has been discussed by R. Zsigmondy. E. Grimaux prepared the hydrosol by heating 8 grms. of methyl orthosilicate with 200 grms. of water in a flask fitted with a reflux condenser; concentrating the liquor to about three-fourths its vol.; and evaporating off the alcohol. The preparation of silica hydrosols has been investigated by W. Spring, E. Ebler and M. Fellner, etc. E. Jordis studied the formation of hydrosols by the peptization of the hydrogel. E. Frémy reported the formation of a hydrosol of silica by the action of water on silicon sulphide, SiS_2 ; hydrogen sulphide gas is evolved at the same time: $\text{SiS}_2 + 2\text{H}_2\text{O} \rightleftharpoons 2\text{H}_2\text{S} + \text{SiO}_2$. J. J. Berzelius made the sol. by the action of silicon fluoride on crystallized boric acid, and removed the boron and fluorine compounds by treatment with a large excess of aq. ammonia. J. Bradfield removed the excess of precipitant used in making silicic acid by means of the centrifuge; F. Bayer, by pressure; and G. Bruni, and B. L. Vanzetti, by freezing. R. Schwarz prepared sols of silicic acid by evaporating a soln. of silicic acid in ammonia over dil. sulphuric acid.

The hydrosol of silica obtained by dialysis has about 5 per cent. of silica, and it can be conc. by boiling in a flask until it contains about 14 per cent. of silicic

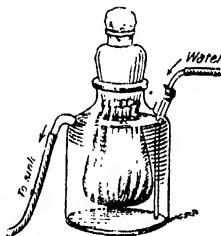

FIG. 51.—B. Proskauer's Dialyzer.

acid, but if boiled in an open flask a ring of insoluble silica forms round the margin of the liquid, and this soon causes the whole to gelatinize. The pure silica sol so prepared is a limpid colourless liquid which gelatinizes, or assumes the hydrogel condition, on standing a few days. The longer the sol has been dialyzed the longer it may be kept without gelatinizing. The passage of silicic acid from the sol to the gel condition is retarded by the presence of a little hydrochloric acid, or alkali hydroxide, and is accelerated, by a little sodium carbonate, or by contact with powdered, inert solids, say, graphite. Dialyzed or soluble silicic acid does not give a luminous beam with Tyndall's optical test, showing that the dissolved particles are not large enough to scatter light. J. H. Bechhold filtered the sol through the so-called colloid filter of biscuit earthenware. The first sign of the coagulation of the soln. appears as a feeble opalescence in the track of the beam, and this gradually increases in intensity. C. F. Böhringer obtained highly dispersed sols of silica by treating silica or other silicon compounds with ammonia to form ammonium silicate and subsequently expelling the ammonia by heat. The coarser particles can be removed by ultrafiltration or dialysis. M. Kröger described the preparation of silica hydrosol.

Silicic acid gels were prepared by H. N. Holmes⁴ by the action of various acids on soln. of sodium silicate of different conc. He measured the effect of temp. and the effect of the conc. of the acid on time of gelatinization. While W. Flemming found the rate of gelatinization depends on the conc. of the silicic acid, the temp., and the catalytic effect of acids or alkalies, H. N. Holmes showed that the dehydrating influence of non-ionized molecules of the acid is of importance. It may happen that precipitates of gelatinous silica prepared in a particular way, or dried at a particular temp., have a definite composition, but each of the compounds so reported represents an arbitrarily selected point on a continuous curve. Thus, according to O. Maschke, if the precipitate be dried in air, it contains from 13 to 36 per cent. of water—the two extremes thus approximate with $2\text{SiO}_2\cdot\text{H}_2\text{O}$ and $\text{SiO}_2\cdot 2\text{H}_2\text{O}$ respectively; and, according to E. Jordis, silica precipitated from dil. soln. of water-glass contains about 94 per cent. of water. F. Ullik dried gelatinous silica in air and found that it approximated to $\text{SiO}_2\cdot\text{H}_2\text{O}$. R. Meldrum said that only the hydrate dried over conc. sulphuric acid has a definite composition, viz. $3\text{SiO}_2\cdot\text{H}_2\text{O}$. J. N. von Fuchs⁵ found a sample precipitated by passing silicon tetrafluoride into water, contained 9.1–9.6 per cent. of water after drying over sulphuric acid for 30 days, and thus corresponded with $3\text{SiO}_2\cdot\text{H}_2\text{O}$; and E. Frémy found that when dried in vacuo, the hydrate corresponded with $3\text{SiO}_2\cdot 2\text{H}_2\text{O}$. V. Merz found that the freshly prepared, and aged silicic acid lost water at different rates. Thus, the percentage water-contents at different temp. was:

	60°	70°	80°	90°	100°	130°	160°	200°
Aged	8.96	—	7.46	6.90	6.24	—	—	3.37
Fresh	—	5.93	—	4.64	4.26	3.5	3.0	—

J. Gottlieb found that after 4 to 5 weeks' drying in a current of air at 100°, a sample contained 4.47 per cent. of water; after drying in an air-bath between 180° and 200°, 4.19 per cent.—this result was taken to correspond with the hydrate $6\text{SiO}_2\cdot\text{H}_2\text{O}$; L. Doveri also found that the product, dried slowly in air at 100°, contained 8.3–9.4 per cent. of water; at 120°, only a trace of water. J. W. Mellor showed that the rate of dehydration of silica precipitated by acid from conc. and dil. soln. of sodium silicate, is faster in the latter case:

Time at 800° (min.)	2	10	20	30
Loss H_2O { from conc. soln.	1.60	4.25	5.72	6.18
{ from dil. soln.	4.49	6.45	8.72	10.04

L. Doveri's product dried over quicklime in vacuo was represented by $3\text{SiO}_2\cdot 2\text{H}_2\text{O}$; W. K. Sullivan's product, obtained by adding hydrochloric acid to a soln. of basic potassium silicate and drying the gelatinous mass in vacuo, or in dry air, was also represented by the same formula; when dried at 100°–120°, $3\text{SiO}_2\cdot\text{H}_2\text{O}$ was said

to be formed. A. Souchay, J. J. Ebelmen, and H. Rose also made observations on this subject. E. Jordis said that the silicic acid which separates from dil. water-glass soln. contains 94 per cent. of water. Most, if not all, of these hydrates are but arbitrarily selected states in a continuous series between the sol of silicic acid and dehydrated silica, and are represented by arbitrarily selected points on a continuous drying curve. According to T. Carnelley and J. Walker, the dehydration or time-temp. curve shows a terrace just below 100° , but is otherwise continuous. A similar terrace is characteristic of many other colloids. B. L. Vanzetti dehydrated silica gels by evaporation and freezing. There was no evidence of the formation of definite hydrates. The composition of the product depended on the initial conc. of the soln. and the age of the gel, and not on the temp. of freezing down to -200° . R. Schwarz and F. Stöwener inferred from their observations on the effect of ammonia on silica gels, that the ageing consists of a dehydration of primary particles which originally held much water, and in a strictly chemical sense, it is probable that dehydration or polymerization also occurs.

In analysis, the soln. containing the silica which separates when the silicate is treated with an acid, is evaporated to dryness with the object of making it insoluble, and the product is baked at 110° . The product is digested with water or dil. acid, and the soluble matters containing calcium, magnesium, and aluminium oxides, etc., filtered off. The residue, silica, is washed and dried. The higher the temp. and the longer the time of drying, the less the amount of silica which passes into soln. There is a limit to the temp. of desiccation on account of the recombination of silica with the bases. W. F. Hillebrand, for instance, showed that magnesia and silica, under these conditions, combine at about 120° . A second evaporation of the soln. is therefore recommended to recover that which passes into soln. in the extraction after the first evaporation. This subject has been fully discussed by J. W. Mellor.

. According to T. Graham,⁵ C. Roberts, etc., if a clear soln. of dialyzed silicic acid be evaporated in vacuo at 15° , a clear transparent jelly is obtained which, when dried over sulphuric acid, has approximately the composition H_2SiO_3 , that is, $\text{SiO}_2 \cdot \text{H}_2\text{O}$, or $\text{SiO}(\text{OH})_2$, and it has been called **metasilicic acid**. According to V. C. Butzureau, an acid of the same composition is obtained by treating gelatinous silicic acid with absolute alcohol. W. K. Sullivan made this hydrate by exposing hard, semi-translucent silica to dry air for some months; and J. J. Ebelmen made it as a glass-like mass by exposing silicic ether to moist air. D. Hayes obtained a crystalline mass, approximating $\text{SiO}_2 \cdot 6\text{H}_2\text{O}$, in the evaporation of sugar soln.; but C. Doelter observed no signs of crystallization after shaking the hydrogel for many months. T. H. Norton and D. M. Roth obtained a hydrate approximating to the composition of **orthosilicic acid**, H_4SiO_4 , that is, $\text{SiO}_2 \cdot 2\text{H}_2\text{O}$, or $\text{Si}(\text{OH})_4$, by washing gelatinous silicic acid successively with dried ether and benzene, and by squeezing the product between folds of filter-paper. The product loses water when exposed to air, and also in contact with absolute alcohol, or some other absorbent medium. H. Hager claimed to have prepared microscopic crystals of the hydrate $\text{SiO}_2 \cdot 3\text{H}_2\text{O}$, or $\text{SiO}_2 \cdot 4\text{H}_2\text{O}$, by the action of conc. hydrochloric acid on a siliceous limestone. C. Struckmann also reported the formation of crystalline needles of a hydrated silica. These results have not been confirmed; the nearest approach which F. Cornu could make was to produce "regularly oriented cracks" when gelatinous silica, derived from many zeolites, contracted on drying. E. Grimaux assumed that the hydrosol was orthosilicic acid which when gelatinized passed into a more complex mol. Nothing is known which precludes the existence of definite crystalline forms of silicic acid, although their existence has not been established by unimpeachable evidence. Like sulphurous and carbonic acids, if the silicic acids are formed, they probably dissociate so readily into water and silica that, as emphasized by V. Lenher and others, there is no satisfactory evidence for assuming the existence of definite hydrates. In any case, it is almost certain that in the hydrogel, the water is not chemically combined with the silica, and the so-called **silicic acids** are to be regarded as adsorption products. Be this as it may,

a large number of compounds of silica with bases—**silicates**—are known—a large number occur in nature as distinct mineral species, and many others have been prepared artificially. These salts can be referred to unknown silicic acids, derived by condensation and dehydration from orthosilicic acid, and called by A. Wurtz ⁶ *les acides polysiliques*.

Many of these silicates are salts of orthosilicic acid. E. Martin has assumed that in the normal *silicon hydroxide*, $\text{Si}(\text{OH})_4$, two of the hydroxyl groups are basic, and two are acidic at low temp., while at higher temp. all are acidic. Combination between molecules of silica may occur through oxygen, but never directly. With these hypotheses, E. Martin has explained the behaviour of silicic acid, prepared in different ways, towards acids, water, and alkalis. He claimed that there is a tendency to form groups of 5SiO_2 . When calcium silicate, made by heating at 1200° , a mixture of calcium carbonate and silica (2 : 1), is dissolved in acetic acid, and the lime removed by ammonium oxalate, there remains a soln. of *silicic acetate*. This slowly hydrolyzes, forming a hydrated silica, $5\text{SiO}_2 \cdot 4\text{H}_2\text{O}$, if dried in a desiccator, or $5\text{SiO}_2 \cdot 2\text{H}_2\text{O}$, if dried at 100° . Hydrated silica prepared by treating calcium silicate with hydrochloric acid, has the composition $5\text{SiO}_2 \cdot 2\text{H}_2\text{O}$, if dried in a desiccator, and $5\text{SiO}_2 \cdot \text{H}_2\text{O}$ if dried at 100° . He also reported $10\text{SiO}_2 \cdot 5\text{H}_2\text{O}$, or $(\text{H}_2\text{Si}_2\text{O}_5)_5$, and $5\text{SiO}_2 \cdot 7\text{H}_2\text{O}$, or $(\text{H}_2\text{SiO}_3)_5$. R. Schwarz and E. Menner ⁷ have dehydrated silicic acid by means of acetone and shown that **metasilicic acid**, H_2SiO_3 , is stable below 15° . Silicic acid made by the action of 80 per cent. sulphuric acid on sodium rhetasilicate at 10° , shows definite breaks in the drying curve at 20° , corresponding with **mesodisilicic acid**, $\text{H}_2\text{Si}_2\text{O}_5$, and **mesotrisilicic acid**, $\text{H}_3\text{Si}_3\text{O}_8$; the former is indicated below under the name datolitic acid, and the latter as garnatic acid. Mesotrisilicic acid is not stable above 32° . There were also indications of the possible existence of two hydrates, $12\text{SiO}_2 \cdot 10\text{H}_2\text{O}$, or **mesohexasilicic acid**, $\text{H}_{10}\text{Si}_6\text{O}_{17}$, and $12\text{SiO}_2 \cdot 9\text{H}_2\text{O}$, or **mesotetrasilicic acid**, $\text{H}_8\text{Si}_4\text{O}_{11}$. For the nomenclature, *vide infra*, Table X.

F. Rinne found that the silicic acid obtained by treating zeolites with acids has a definite structure, and is doubly refracting; while E. Jorlis showed that the silicic acids derived from the different alkaline earth silicates have different tendencies to pass into the sol. condition. According to G. Tschermak, different silicic acids—**G. Tschermak's silicic acids**—are obtained by treating certain natural silicates with hydrochloric acid, and these acids may be regarded as the fundamental acid of the particular silicate in question. G. Tschermak prepared these acids by treating the powdered silicate with hydrochloric acid at about 60° ; washing the liberated silica hydrates; and allowing the product to dry slowly in air. The slope of the curve, showing the relation between the loss of weight and time, changed abruptly at a certain temp. which G. Tschermak supposed represented a transition from the evaporation of adsorbed water to dehydration by the loss of chemically combined water. G. Tschermak further supposed that at the transition temp. the composition of the hydrated silica corresponded with that of the mineral regarded as a salt of the acid. The supposed acids were further distinguished by their behaviour towards methylene blue—**A. Suida's reaction**—for those acids richest in water were found to be coloured more intensely than acids with less water. V. Iskyul studied the solubility of silica in many minerals. According to G. Tschermak:

(1) **Orthosilicic acid**, H_4SiO_4 , is obtained by the decomposition of silicon tetrachloride by water, and by the action of hydrochloric acid on orthosilicates—natrolite, diopase, scolecite, willemite, monticellite, calamine. Its sp. gr. at 17° is 1.576, and it is coloured bluish-black by methylene blue. (2) **Metasilicic acid**, H_2SiO_3 , is obtained by the action of hydrochloric acid on anorthite, olivine, or hovrile. Its sp. gr. is 1.813, and it is coloured prussian-blue by methylene blue. (3) **Datolitic acid**, $\text{H}_3\text{Si}_3\text{O}_8$, is obtained from datolite, gadolinite, eucelase, and homilite (*vide supra*). It has a sp. gr. of 2.197 and forms a light prussian-blue tint with methylene blue. (4) **Leucitic acid**, $\text{H}_4\text{Si}_4\text{O}_{10}$, is a polymer of metasilicic acid obtained from leucite. Its sp. gr. is 1.834, and it is coloured pale prussian-blue by methylene blue. (5) **Serpentinic acid**, $\text{H}_4\text{Si}_4\text{O}_{12}$, a polymer of leucitic acid, is

obtained from serpentine, bowenite, or antigorite. Its sp. gr. is 1.809, and it forms a light prussian-blue tint with methylene blue. It does not gelatinize like metasilicic acid. (6) *Garnitic acid*, $H_4Si_3O_8$, derived from grossular, epidote, zoisite, or prenite (*vide supra*). It has a sp. gr. 1.910, and it is stained pale or light blue by methylene blue. (7) *Albitic acid*, $H_2Si_2O_7$, is obtained from albite. It has a sp. gr. 2.043, and it is not coloured by methylene blue. (8) *Pectolitic acid*, $H_2Si_2O_7$, is derived from pectolite or wollastonite. It is not stable when isolated. Its sp. gr. is 1.810–1.816. It forms a deep prussian-blue tint with methylene blue. (9) *Sepiolitic acid*, $H_2Si_2O_7$, is obtained from meerschaum. Its sp. gr. is 1.763, and it forms a prussian-blue tint with methylene blue. (10) *Chrysotilic acid*, $H_2Si_2O_7$, is derived from chrysotile or serpentine asbestos. Its sp. gr. is 1.725 (17°), and it forms a prussian-blue tint with methylene blue. (11) *Harmotomic acid*, $H_2Si_2O_7$, is derived from harmotome, and it forms a pale blue with methylene blue. (12) *Heulanditic acid*, $H_{16}Si_8O_{17}$, is derived from heulandite, and it forms a pale prussian-blue with methylene blue.

J. M. van Bemmelen doubted if these silicic acids are chemical individuals; and H. le Chatelier said that no change in the appearance or consistency of gelatinous silicic acid could be detected after heating 6 hrs. at 320°; and he concluded that silica, like chromic trioxide, does not form hydrates, but on account of its insolubility remains in an extremely fine state of subdivision when precipitated. According to E. Jordis, the work of J. M. van Bemmelen on the vap. press. of the gels of silica shows that the amount of water in a gel is proportional to the partial press. of the water in the surrounding atm. O. Mügge has shown that the differences in the rates of drying observed by G. Tschermak depend on the temp.; and the observed changes cannot be supposed to differentiate between absorbed water and chemically combined water, and they give no basis for the deduction of the formulæ arbitrarily assigned by G. Tschermak. As J. M. van Bemmelen has shown, silica hydrogels are colloidal absorption compounds of indefinite composition, and changes in the rate of dehydration, and the effects on methylene blue are probably due to changes in the mechanical structure of the hydrogel brought about by the gradual removal of water. J. Splichal found that the character of the silicic acid depended on the nature and conc. of the acid employed for decomposing the silicate. P. Pascal found that the silicic acids behave magnetically like mixtures of the anhydrous oxide and water, and lend no support to the assumption that definite silicic acids exist. J. S. Anderson obtained no evidence of the formation of definite hydrates in his study of the adsorption and evolution of liquids from silica gels. H. N. Holmes studied the formation of gel silicic acids. Consequently, the real existence of G. Tschermak's acids has not been satisfactorily established, but the idea may have some uses in developing a system of classification of the silicates.

F. Mylius and E. Groschuff⁸ have shown that if, at 0°, the eq. of two mols of hydrochloric acid be added to a soln. containing one mol of sodium silicate, $Na_2Si_2O_5$, with the eq. of 2 grms. of silica per 100 c.c., the resulting **α -silicic acid** does not precipitate albumen from a soln. containing the white of an egg; but on standing some time, or on warming, the α -silicic acid acquires the property of precipitating albumen. It is therefore considered that α -silicic acid passes into **β -silicic acid**. The β -acid is also precipitated by methylene blue and by sodium hydroxide. The electrical conductivity and the lowering of the f.p. change in the passage of α -silica to the β -acid. The α -acid gives results which correspond with a mol. wt. of 155; the β -acid with a mol. wt. approaching 49,000. Consequently, the transformation is considered to be due to a polymerization of the α -acid. T. Graham concluded that the *molecular weight of colloidal silica* must be very great because its acidity is neutralized by such small proportions of alkali, and A. Sabanejeff concluded from the lowering of the f.p. that the mol. wt. of silicic acid must exceed 30,000. The attempt to determine the mol. wt. of colloidal suspensions by osmotic press. phenomena is quite illogical because the whole argument on which the methods are based, is alone applicable to homogeneous soln. and not to homogeneous suspensions. R. Schwarz and O. Liede conclude from the behaviour of silica gel when slowly dried at ordinary temp., that the ageing process consists in the condensation of $(SiO_2)_x$ to $(SiO_2)_{2x}$, and that this occurs

without any change in the appearance of the gel; further changes in the system $\text{SiO}_2 \cdot \text{H}_2\text{O}$ then occur, leading to the formation of $(\text{SiO}_2)_x$, which is indicated by the incipient formation of cloudy particles in the colourless, transparent mass. Precisely similar phenomena are observed when the gel is dehydrated by being heated, but, for some unexplained reason, a much greater loss of water appears to be necessary in this case before the end-point is reached. A. Schwarz and Ö. Liede obtained β -silicic acid by passing silicon tetrafluoride into boiling water. The product dissolved less readily in hydrofluoric acid, sodium hydroxide soln., or aq. ammonia than the ordinary α -silicic acid. From the conductivity of the ammoniacal soln., they regarded it as a polymerized form analogous to β -stannic acid.

T. Graham⁹ said that the hydrosol is coagulated on standing, and this the more quickly, the more conc. the sol, or the higher the temp. This was confirmed by W. Flemming. T. Graham found that a 12 per cent. sol at ordinary temp. was coagulated in a few hours, while 5-6 per cent. sol required 5-6 days, a 2 per cent. sol required 2-3 months, and a 1 per cent. sol required 2 or more years. According to O. Maschke, the coagulation of the sol in glass vessels is largely determined by the dissolution of alkalis, etc., from the walls of the containing vessels. According to E. Jordis and co-workers, T. Graham's observation that the longer the silicic acid is hydrolyzed the more stable the product, is explained by the increase in the amount of alkali derived from the glass. The contradictory reports are in some cases due to the presence of unsuspected impurities. E. Jordis and co-workers concluded that T. Graham's hydrosol is contaminated by acids or bases, and E. Grimaux's hydrosol is contaminated with organic matter. When the sol is dried over sulphuric acid in vacuo, T. Graham found that the insoluble residue contained 21.99 per cent. of water; and C. Roberts, 24 per cent. of water. W. Kühne found that T. Graham's hydrosol is not coagulated by alcohol, glycerol, sugar, gum, or caramel; alumina hydrosol, ferric oxide hydrosol, gelatine, albumen, and casein were found by T. Graham to coagulate silica hydrosol. W. Kühne, and B. Kempe found that silica hydrosol is not gelatinized by salts with an alkaline reaction, by alcohol, ammonia, sugar, albuminose, glycerol, peptone, and alkali albuminates, but it is gelatinized by glue, and by neutral salts. F. Dienert and F. Wandenbulcke discussed the effect of dissolved salts on the colloidal silica in natural waters, and sea-water.

According to L. F. Werner, acids have a very powerful peptizing effect upon the hydrosol of silicic acid. In the case of the strong acids, this effect is most marked at a medium conc. Alkalis also have a strong peptizing influence; the effect is greatest for medium and low conc. for the highly ionized bases, and in the case of the slightly ionized bases the effect is great in all but the lowest conc. tried. Salts have no effect in presence of acids, but in the presence of bases the congealing effect is hastened. Potassium salts of several negative radicles decreased the time required for gelation. The chlorides of various metals, with the exception of ferric and cupric chlorides, decreased the time of gelation. Sodium hydrophosphate and dihydrophosphate have strong congealing powers, but normal sodium orthophosphate has the opposite effect. The di- and tri-sodium citrates accelerate the setting greatly, the effect decreasing with the conc.; but, in the case of the monosodium salt, the time for setting is the same for all conc. The acetates of the various metals have the greatest congealing effect (excepting that of mercury). Inorganic salts produce but little effect. The alkali salts of the organic acids produce powerful accelerating effects, except the carbonates and hydrocarbonates, which have a peptizing effect in soln. of medium to low conc. F. Dienert and F. Wandenbulcke found that alkali carbonates accelerate the flocculation of colloidal silica, and salts with an acidic reaction like aluminium sulphate hinder the change. J. Amar found the velocity of coagulation to be proportional to the lowering of the surface tension by the coagulant.

According to W. Flemming, silica hydrosol is coagulated by graphite powder, and by alkali and alkaline earth carbonates; hydrogen and hydroxyl ions have a

catalytic effect on the rate of coagulation, for as the conc. of hydrogen ions increases, the coagulation is first retarded and then accelerated; as the conc. of hydroxyl ions increases, the coagulation is first accelerated and then retarded. As shown by T. Graham, silicic acid is readily peptized by sodium hydroxide and ammonia, but it adsorbs lime from suspended calcium carbonate; is precipitated by calcium hydroxide, and basic dyes; and is coagulated by soln. of carbonates of the alkalies or alkaline earths. T. Graham said that his sol was coagulated by carbon dioxide, while H. Kühn said that this agent does not coagulate the silica sol derived from silicates; nor was E. Grimaux's hydrosol coagulated by carbon dioxide. The reaction has also been studied by W. Flemming, E. Jordis, etc. H. Kühn found that the sol is coagulated by the electric current or by freezing, and by alcohol, or sulphuric acid. A. Löttermoser, and N. N. Ljubavin also found the hydrosol precipitates most of the contained silicic acid when frozen. F. Hoppe-Seyler showed that the sol is coagulated by schizomycetes fungi. N. Pappadá and C. Sadowsky found that the speeds of coagulation and gelatinization of silica hydrosols follow the same laws. The coagulation of silicic acid sol was studied by O. M. Smith, etc. According to N. Pappadá, soln. of non-ionized organic substances do not coagulate silica sol, but soln. of ionized salts coagulate negative colloidal silicic acid, and, with a given family of salts, the action is all the more marked the greater the at. wt. of the salt—*e.g.* the cations (Cs^+ , Rb^+ , K^+ , NH_4^+ , Na^+ , and Li^+) act with decreasing intensity in the order named; similarly, the action is more marked the greater the electrical charge on the ion, thus trivalent ions are more active than bivalent ions, and these in turn more than univalent ions. Thus, W. B. Hardy found aluminium sulphate acted immediately; copper sulphate or copper, cadmium, or barium chloride acted in 10 mins.; magnesium sulphate in 2 hrs.; and potassium or sodium sulphate in 24 hrs. The gelatinization seems to be independent of the nature of the anion. S. Glixelli found the acidity of silica is increased in the presence of uni- or bi-valent ions of neutral salts. The protective action of trivalent iron salts on a sol of silicic acid was investigated by E. Guerry and E. Toussaint. H. W. Foote, S. R. Scholes, and R. W. Langley have discussed the precipitation of ferric and aluminium hydroxides along with colloidal silica so as to form solid soln. P. Rohland found that silica hydrogel derived from clay adsorbs colloids—*e.g.* soap, starch, and dextrin—complex dyes—*e.g.* aurin, fluorescein, and cochineal—carbonate-ions, hydrocarbonate-ions, tetraborate-ions, and phosphate-ions. Organic substances containing oxygen—*e.g.* alcohol and acetone—are adsorbed. Silica gel is impermeable to organic substances which do not contain oxygen, and sat. hydrocarbons—*e.g.* toluene, and carbon disulphide. E. Dittler, and H. Rheinboldt and E. Wedekind studied the adsorption of organic colouring matters by hydrogels of silica; L. Berényi, and J. McGavack and W. A. Patrick, the adsorption of sulphur dioxide; L. Berényi, L. Y. Davidheiser and W. A. Patrick, ammonia; W. A. Patrick, sulphur dioxide, ammonia, and carbon dioxide; H. Briggs, hydrogen and nitrogen at low temp.; P. C. Ray, nitrogen peroxide; and A. B. Ray, and H. Briggs, organic vapours; W. A. Patrick and D. C. Jones, formic, acetic, butyric, and benzoic acids, and iodine, from various solvents; nitrobenzene and benzene from kerosene; and acetic acid from carbon disulphide; D. C. Jones, acetic acid from gasoline; W. A. Patrick and J. S. Long, butane. N. K. Chaney and co-workers showed that while carbon adsorbs benzene and rejects the water from a mixture of benzene and water, silica gel adsorbs water and rejects the benzene. C. M. Faber and co-workers measured the variation in the efficiency in the adsorption of water, benzene, nitric acid, and nitrogen peroxide with use. There is a promising field of application for silica gel as an absorbent for condensable vapours from gases; and as a refining agent for liquids, particularly petroleum oils. It also has uses in the recovery of benzene hydrocarbons from coal gas, or coke-oven gases for use as a motor oil. The adsorption of benzene and other vapours has been discussed by E. C. Williams, R. Furness, E. B. Miller, F. Meyer, and N. K. Chaney; and of sodium fluosilicate, and potas-

sium metasilicate, by M. A. Rakuzin. According to E. M. Faber and H. G. Olsen, carbonyl chloride and nitrogen peroxide are absorbed by silica gel. According to J. N. Mukherjee, precipitated silica adsorbs acetic, citric, hydrochloric, and nitric acids, but A. F. Joseph and J. S. Hancock stated that purified silica has no effect on a soln. of an acid, and that the reported effects are due to the use of inadequately purified silica; the effect of silica on a soln. of an electrolyte is to produce free acid and a complex silicate of low solubility and alkaline reaction. W. Bachmann showed that the amount of adsorption of water, benzene, chloroform, ethyl iodide, and acetylene tetrabromide by silica gel is proportional to the density of the liquid; W. A. Patrick and J. S. Long found that the adsorption of *n*-butane is greatest with silica gel with about 2 per cent. of water; and J. McGavick and W. A. Patrick found 7 per cent. of water to be most favourable for the adsorption of sulphur dioxide between -80° and 100° . D. C. Jones studied the effect of the dispersibility of the silica gel on its adsorptive power. J. H. Frydlander, F. Meyer, W. Paulsen, E. B. Miller, R. Furness, N. K. Chaney, and E. C. Williams discussed the use of silica gel as an absorbent for industrial purposes. Their uses, said H. N. Holmes and J. A. Anderson, include solvent recovery, the drying of air for blast furnaces, and for vacuum ice machines; the recovery of sulphur dioxide and nitrogen oxides; removing offensive odours from air; removing sulphur compounds from petroleum fractions; decolorizing certain liquids; the recovery of gasoline from natural gas, etc.

E. Jordis and E. H. Kanter¹⁰ inferred that because the electrical conductivity of silica hydrosol increases to a maximum by the successive additions of small quantities of hydrochloric acid, then falls to a minimum, and again increases, hydrochloric acid and silica unite chemically. F. Mylius and E. Groschuff likewise assumed the formation of an intermediate chloride in the hydrolysis of silicon tetrachloride by water. J. Meyer, however, believes that the obstinate retention of hydrochloric acid by silica gel is an adsorption phenomenon, not chemical combination. The washing has also been discussed by E. Jordis, R. Zsigmondy and R. Heyer, etc. According to J. M. van Bemmelen, the amount of a substance which is absorbed from a soln. by a given quantity of a silica gel (dried at 100°) depends on the temp. and conc. of the soln., as well as on the nature, physical state, and previous history of the absorbent gel. The amount absorbed increases with the conc. of the soln., but not proportionally since relatively more is absorbed from dil. soln. than from conc. soln., so that the ratio of the amount of salt absorbed to the conc. of the soln. decreases as the conc. increases. Alkalies are strongly adsorbed, and soln. of salts of the feeble acids are decomposed and part of their alkaline base is selectively absorbed by the silica—e.g. alkali carbonates, phosphates, borates, and calcium carbonate. Absorption thus appears as a kind of incipient combination. When the absorption has progressed far enough, the silica gel may pass into the sol condition, as was observed by T. Graham in an experiment where one part of sodium hydroxide in 10,000 parts of water at 100° , converted 200 parts of anhydrous silica into the sol state. The absorption or adsorption with quartz is much less than with amorphous silica, but it follows the same general law—vide the chemical properties of silica. R. Schwarz and H. Stock found silicic acid sols act as a positive catalyst on the photochemical decomposition of silver bromide; and E. O. Holmes and W. A. Patrick, on acetone, acetic acid, and nitric acid.

J. S. Anderson¹¹ found the sp. gr. of silica gel sat. with water to be 1.500; of the dried gel, 1.980; and of the gel substance, 2.048. E. Berl and W. Urban found the sp. gr. of silica gel dried at 25° , is 2.465; dried at 800° , 2.390; dried at 1000° , 2.271; evaporated with hydrochloric acid and ignited, 2.627. The sp. gr. of the opals ranges from 1.9 to 2.5—the gem opals have a sp. gr. 2.1–2.2. The sp. gr. of hydrated silica which has been dried lies between 1.7 and 1.9. According to F. Auerbach, the hardness of opal lies between 5 and 6. An opal from Mexico had a coeff. of elasticity of 3,880,000; and a torsion coeff. of 1,829,000. In their study of the musical tones produced by vibrating silicic acid gels, H. N. Holmes

and co-workers found that these gels vibrate as rigid solids. The vibration frequency varies inversely as the diameter of the column of gel, and tension exerts an influence; the vibration frequency varies directly as the conc. of the silicic acid, increases with an excess of mineral acids, and decreases with an excess of organic acids. According to H. Kopp, and J. Joly, the sp. ht. of hyalite is 0.2033, and of opal 0.2375.

The separation of aq. soln. from highly hydrated gels—the so-called *syneresis*—increases with increased conc. of silicic acid, increases with excess of mineral acids, and decreases with excess of organic acids. Neither J. Thomsen nor G. Bruni and N. Pappada could detect any thermal change during the coagulation of silicic acid sols, but others have noted an appreciable thermal effect. T. Graham, for instance, noted a rise of temp. during the coagulation of the hydrosol of silica. The heats developed during the coagulation of a 3 per cent. soln. of silicic acid prepared from potash water-glass and a 2.4 per cent. soln. of silicic acid from soda water-glass, are:

	Sol with 3 per cent. silicic acid from potash water-glass.		Sol with 2.4 per cent. silicic acid from soda water-glass.		
Per cent. aluminium sulphate soln.	3.4	6.8	1.7	6.8	13.6
Heat of coagulation	16.8	27.1	17.9	30.7	32.8 Cals.

Observations on this subject have been made by F. Dörinckel, E. Wiedemann and C. Ludeking, O. Mulert, L. Kahlenberg and A. T. Lincoln, etc. Similar results were obtained by coagulating the sol with a 6.8 per cent. soln. of alkali sulphate. J. Spichal found that the hydrosols of alumina and silica mutually precipitate one another, and the precipitation is most rapid, and the viscosity greatest, when the molar ratio $\text{Al}_2\text{O}_3 : \text{SiO}_2$ is as 1 : 3. M. Kröger found that the gelatinization of a mixture of silica and tungstic hydrosols proceeds so that the time-tungstic acid curve passes first through a minimum, then as the conc. of the tungstic acid increases, it passes through a maximum and then falls continuously. A. W. Thomas and L. Johnson discussed the mutual precipitation of colloidal soln. of ferric oxide and silica.

The process of gel-formation in silicic acid and the gelatines has been studied ultra-microscopically by W. Bachmann. The amplitude of the Brownian movements of the ultra-microscopic particles diminishes and the size of the particles increases by flocculation during the ageing of the gel; the structure gradually becomes less distinct, and at last ultra-microscopically homogeneous owing to the close-packing of the jelly elements. The supposed foam structure is a diffraction phenomenon. Gel silicic acid obtained by dialysis, with a collodion membrane, and dried over sulphuric acid, polarizes light feebly, thus indicating a very minute heterogeneity. The index of refraction of the opals is low. According to A. des Cloizeaux,¹² the index of refraction for red light varies from about 1.442–1.450; and, according to A. K. Zimanyi, for the yellow sodium light, from 1.4536–1.4580 between 21° and 28.5°. A hydrosol from soda water-glass with 0.4134 gm. of silica per 31.3630 grms. of soln., has a sp. gr. of 1.004923 at 24.1° (water at 24.1°=0.99730), and an index of refraction for sodium light, 1.33389; and for the H_α -line, 1.33205; the H_β -line, 1.33800; and the H_γ -line, 1.34139 (water for H_α =1.33080). Observations were made by C. Abbati, F. Cornu, M. Lazarevec, etc. According to W. W. Coblentz,¹³ quartz has small absorption bands between 2.9 μ and 6.65 μ , and the group of atoms characteristic of quartz maintains its characteristics, more or less sharply defined, in the mineral silicates. In opal, the bands characteristic of water are superposed upon those for quartz, and since opal shows no signs of crystallization it is inferred that the water is in a state of solid soln., since the contained water is a function of the vap. press. The absorption spectra of opal, selenite, and the zeolites are alike as regards the position and intensity of the water bands. C. Wissinger studied the absorption spectrum of silica hydrogel. Opal is a non-conductor of electricity. The hydrosol of silica conducts electricity. F. Mylius and E. Groschuff¹⁴ found the conductivity in

presence of sodium chloride changed from 14032×10^{-6} mhos when freshly prepared to 14081×10^{-6} mhos after standing 6 days at a temp. of 16° . Silica hydrosol resulting from the action of 40 grms. of silicon tetrachloride on 2 litres of water had a conductivity of 6.2×10^{-6} mhos; after 14 days' hydrolysis the conductivity altered to 3.2×10^{-5} ; and after 22 days' hydrolysis, 1.7×10^{-6} mhos.

A. C. Becquerel,¹⁵ and W. Spring found that an alkaline soln. of silica hydrogel acquires a positive charge, and when an electric current is passed through the soln., the gel collects on the cathode. W. B. Hardy, however, showed that with distilled water, the thoroughly washed hydrogel is iso-electric, and with the smallest trace of free alkali in the water, it becomes electronegative. S. E. Linder and H. Picton, N. Pappadá, and A. Löttermoser also found that dialyzed silicic acid collects on the anode. W. Biltz, and W. R. Whitney and J. C. Blake made observations on this subject. O. Lösenbeck measured the electrical conductivity of silica sols. He found the conductivity of hydrochloric acid soln. of conc. up to $\frac{1}{100}N\text{-HCl}$ is reduced by the presence of silicic acid soln. The magnitude of the change decreases with time, being at first rapid, and then slows off to a limiting value. The particles of silicic acid are negatively charged, and the charge is steadily reduced by the addition of hydrochloric acid until the isoelectric point is reached. With further addition of acid the sign of the charge changes, and the charge increases until the positive value is greater than the original negative value. The contact potential of the particles in different conc. of the same preparation is dependent on the conc. of the sol, in the sense that the isoelectric point of different sols lies at greater conc. of hydrochloric acid the greater the conc. of the sol. The observed results are explained by assuming that the silicic acid particles are sat. with hydrochloric acid, like a sponge, and that this acid is taken up slowly. The hydrogenions are expelled from these sponges with a definite tension, so that the contact potential between particle and soln. may be approximately represented by W. Nernst's formula. W. Grundmann studied the electrical properties of sols of silicic acid, and showed that the charge in a hydrochloric acid soln. changes on keeping, becoming at first more negative, reaches a maximum, and then changes in the opposite direction. Colloidal silica in dil. acid and alkaline soln. is electronegative, and during electrolysis accumulates about the anode, and J. Billitzer showed that in alkaline and feebly acid soln.—say, up to $0.1N\text{-HCl}$ —the gel is electronegative; with a greater conc. of acid—say, $\frac{1}{2}N\text{-HCl}$ —the gel is electropositive; and somewhere between these limits an isoelectric point occurs where the liquid is electrically neutral.

These facts have been applied industrially by B. Schwerin to remove impurities from clays, etc. When soln. of chlorides are added to water with the clay in suspension, certain impurities settle readily, others remain in suspension. If the added salt also changes the electrical state of certain impurities so that, say, free silica becomes electropositive while the clay remains electronegative, the passage of a current through the soln. will enable the electronegative clay to collect about the anode, while the electropositive impurity accumulates about the cathode. W. R. Ormandy has discussed the application of the process.

The great variations in the proportion of water in different varieties of opal, and in the same varieties from different localities, prevents the application of a definite formula— $\text{SiO}_2 \cdot n\text{H}_2\text{O}$. Thus, E. Frémy¹⁶ found that after drying in vacuo, hyalite opal contained 1.5 per cent. of water; a gem-opal from Mexico, 6.3 per cent.; and a sample of opaque and glassy geyserite, 12.1 per cent. Attempts to find if the dehydration curves of the opals show any signs of breaks or singularities, have given negative results. It is therefore inferred that *opals are not definite hydrates of silica*. In 1877, J. B. Hannay gradually heated a sample of opal with 8.24 per cent. of water at 100° in a current of dry air, and determined the water lost every 5 mins. and later every 20 mins. G. d'Achiardi confined seven different samples of Tuscany opal in desiccators, and found the loss of weight after definite intervals of time extending over 200 days. The results with a sample of kieselguhr

from Castel del Piano, Monte Amiata; a sample of black opal from San Piero, Campo; a milk-white opal from Fundorte; and a water-clear opal from San Piero, are plotted in Fig. 52; there is here no evidence of any discontinuity in the curves. G. d'Achiardi also obtained the same conclusion by measuring the amount of water lost during definite intervals of temp. rising from 80° to 320°. G. Tammann kept samples of hyalite and opal in desiccators over sulphuric acid of different conc. so as to allow the dehydration to occur in atm. of definite humidity, Table IX.

According to J. M. van Bemmelen,¹⁷ the gel of silica hydrate under the microscope appears to have a cellular structure and to be composed of a kind of network—*Wabenstruktur*—formed by two soln.—the one more conc. forms the walls of a mass of cells which enclose the other more dil. soln. O. Bütschli also noticed that a mesh-like structure appears at a certain stage in the drying of gelatinous silica, and dis-

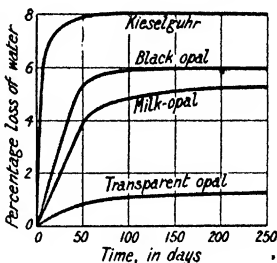

FIG. 52.—The Dehydration Curves of Some Varieties of Opal Confined over Sulphuric Acid.

TABLE IX.—LOSS OF WATER BY OPALS IN ATMOSPHERES OF DIFFERENT HUMIDITY.

Conc. of sulphuric acid per cent.	Vap. press. of sulphuric acid in mm. at 25°.	Time in days.	Percentage loss in weight.
20.3	21.24	6	2.96
29.2	18.33	9	3.90
40.6	13.15	7	9.95
50.1	8.77	6	10.75
60.4	4.32	6	11.60
70.3	1.74	8	12.09
85.1	0.18	22	13.30

appears at a later stage of the drying. He also found that the natural opals exhibit a very fine cellular structure which requires the very greatest magnification to be rendered visible—hydrophane, for example, with a magnification of 2090 diams., shows the cellular structure and is very little different from gelatinous silica. The two are illustrated side by side in Fig. 53. W. Biltz and W. Geibel studied the ultra-microscopic structure of silica hydrogel. According to O. Bütschli, a gel with 30-40 mols. of water can be separated by cutting; with 20 mols. it is somewhat stiff; with 12 mols. it is brittle; and with 6 mols. it can be triturated to form a dry powder. There is a stage in the dehydration where the gelatinous silica begins to lose its transparency and become turbid. This temp. depends on the nature of the gel, its mode of preparation, the rate of dehydration, the age of the specimen, etc. The vol. of the gel shrinks very little if dehydrated further, since the gel now forms empty spaces which gradually fill with air, and produce the turbidity; or, as R. Zeigmondy infers from his ultra-microscopic examination of the phenomenon, the turbidity is produced by the accumulation of liquid separated by films of air. By prolonged

FIG. 53.—The Cellular Structure of Opal (left) and of Partially Dried Gelatinous Silica (right).

heating, the gel gradually loses its air-spaces, and at the same time its absorptive power for water, *e.g.* the amounts of moisture adsorbed by precipitated silica calcined at different temp. are :

	110°	600°	700°	800°	900°	1200°
Adsorption . .	18.35	15.93	15.34	12.85	3.96	0.00 per cent.

J. Duclaux assumed that reversible gels contain (i) a liquid—water or a solvent ; (ii) an insoluble solid, forming with the liquid an irreversible gel or sponge-like structure of ultra-microscopic cells ; and (iii) a soluble solid dissolved in the solvent of the gel. The mols. or miscellæ of this substance, which may be either crystalloid or colloid, are too large to be able to escape from the cellules of the sponge, but they are small enough for their soln. to have a certain osmotic press. in relation to the pure solvent. This soln. is the “plasm” of the gel, and its swelling and expansion in a solvent are due to the osmotic press. of the plasm. The limit of expansion is reached when equilibrium is attained between this osmotic press. and the cohesion of the cellular structure of the gel. If the osmotic forces are strong enough, continued inflation of the cellules may result in the dissolution of the gel, and the separation of the soluble and insoluble constituents.

P. P. von Weimarn¹⁸ argued that many of the so-called amorphous powders probably have a crystalline structure, for they may really be so fine-grained that, under the microscope, the form of the crystalline grain appears to be rounded owing to diffraction and other phenomena. The crystalline nature of such precipitates must be proved in other ways since the fineness of the grain prevents the satisfactory application of the microscope. Under the microscope, these precipitates exhibit various characteristics peculiar to crystalline structures—*e.g.* they have a network, honeycomb, rayed, or dendritic structure unless they are formed of detached granules. Hence, says P. P. von Weimarn, such formations are to be regarded as a result of an orientation of the finest granules. R. Schwarz and F. Stöwener studied the *ageing of silica gels*, and showed that during the ageing water is lost even though the gel be under water ; the dehydration is regarded as a preliminary stage in the formation of crystals.

The vap. press. of hydrated silica varies continuously and regularly with the conc. of the contained water, so that the solid silica and the water really form a univariant system with only one component—water—and two phases—vap., and water of hydration. If the water vap. be in equilibrium with the water of hydration at a vap. press. p , and some water is removed, the solid loses some water of hydration, but the vap. press. is not restored to p since it acquires a lower value p_1 . If a definite hydrate were in question, the vap. press. would remain at p until all the hydrate had been decomposed.

Partially dehydrated silica hydrate is very hygroscopic. The silica remaining when the organic derivatives of silicon have been submitted to combustion analyses are sometimes very hygroscopic, thus, J. A. Meads and F. S. Kipping report¹⁹ that the product from diphenylsilicenediol on exposure to air, had a constant weight only after the absorption of 16.2 per cent. of moisture. Silica hydrate which has been dried in air becomes warm when moistened with water. Silica obtained by calcining the hydrate at about 500°, can take up about 14 per cent. of water, and silica which has been calcined at a higher temp. can take up only 2 per cent. The water is more easily driven from the rehydrated silica heated to, say, 100° than from the original hydrate. If silica hydrate which has been heated to 200° be exposed to a moist atm., water is again absorbed, and the vap. press. of the hydrate is greater than that of the original hydrate of the same composition. This has been taken to show that the water is less firmly retained by the product of the rehydration of partially dehydrated silica hydrate.

J. M. van Bemmelen²⁰ has determined the equilibrium conditions of the hydrogel of silicic acid. He started with a freshly prepared sample containing the eq. of $\text{SiO}_2 + 100\text{H}_2\text{O}$; portions were placed in desiccators over sulphuric acid of different

conc., and accordingly also of different vap. press. Under these conditions, equilibrium occurs when the vap. press. of the gel is equal to the vap. press. of the sulphuric acid over which the gel is confined. The dehydration curve follows the direction of the arrows along *ABCD*, Fig. 54. While *AB* is a continuous curve representing

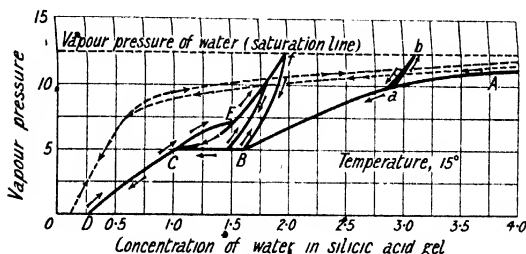

FIG. 54.—Curve of the Dehydration and Rehydration of the Hydrogel of Silicic Acid.

the equilibrium press. during dehydration, rehydration does not follow along the same path in the reverse direction, but rather strikes a shorter course, say, *ab*, to reach the saturation curve representing the vap. press. curve of water at 15°; subsequent dehydration follows nearly along the same path, *ba*, but a little to the left. Returning to the first dehydration curve *AB*, this passes to *BC*, which is nearly horizontal, showing that here the removal of water has very little influence on the vap. press. of the hydrate. As the gel, previously clear and transparent, loses water along *BC*, it begins to develop an opalescence in its interior, owing to the formation of small bubbles of air or water vap. where previously liquid water was present. The opalescence gradually spreads outwards until the whole mass appears yellow by transmitted, and blue by reflected light. As the dehydration continues, the gel at *C* becomes white, and, travelling along *CD*, it becomes opalescent, and finally as clear as glass. The *CD*-curve represents a reversible reaction in that rehydration *DC* and dehydration *CD* follow the same track. At *D*, the gel has about the eq. of $\text{SiO}_2 + 0.2\text{H}_2\text{O}$. If the gel between *B* and *C* is dehydrated, it takes a short cut to the saturation curve, for after travelling along *DC*, it will pass from *C* to *E* to *f*; on dehydration at *E*, the curve travels as indicated by the arrow so that the process is not reversible. Dehydration from any particular state is represented by arrows directed downwards and to the left, and rehydration by arrows directed upwards and to the right. The curves dotted in the diagram represent, in the same way, the dehydration and rehydration of the hydrogel of silicic acid ten months old. J. Amar measured the speed of dehydration; and J. S. Anderson, the adsorption and evolution of moisture by silica gels. The two curves do not coincide, but show a decided hysteresis in the sense that water is evolved at a lower press. than that at which it is adsorbed. Similar results were obtained with alcohol and benzene. J. S. Anderson also measured the rates of adsorption and evolution of these three substances. E. Berl and W. Urban measured the hygroscopicity of silica gels. W. A. Patrick and F. V. Grimm found the heats of wetting of silica gel in Cals. per gram of gel to be 19.22 for water; 22.23 for ethyl alcohol; 11.13 for benzene; 8.42 for carbon tetrachloride; and 17.54 for aniline.

The net result of the interesting work of J. M. van Bemmelen is to show that the hydrogel of silicic acid is an unstable system of the general composition $\text{SiO}_2 \cdot n\text{H}_2\text{O}$, where the value of *n* is determined by the physical conditions, and the previous history of the gel. M. Guichard investigated the adsorption of water by silica gels in relation to time, temp., and age. Similar phenomena were observed with the hydrogels of magnesium, beryllium, aluminium, manganic, ferric, chromic, cupric, zirconium, and stannic hydroxides—with variations, of

course, in individual cases. According to R. Zsigmondy, the peculiar dehydration curves obtained by J. M. van Bemmelen are best explained by assuming that the vap. press. of the retained water is diminished by the presence of fine capillaries. If the capillary formula holds for pores down to 5μ , the vap. press. would be depressed 6 mm. The difference between the curves for dehydration and subsequent rehydration are explained by assuming the liquid fails to wet the walls completely in the second case owing to the absorbed air. The irreversibility of the changes is due to the union of the amicroscopic particles to form larger particles—probably crystalline. J. S. Anderson, from his experiments on the evolution and adsorption of moisture by silica gels, inferred that the gel is made up of pores of varying sizes which are largest where the hysteresis on the drying curve begins, and smallest where it ceases. He measured the lowering of the vap. press. of water, alcohol, and benzene produced by the presence of fine capillaries in the gel, and hence calculated the radius, ρ , of the pores from $\log_e(p_0/p) = 2\sigma D_v/D\rho p_0$, where ρ represents the radius of the pore; σ , the surface tension of the liquid at the temp. of the experiment; D_v , the sp. gr. of the liquid; D_v , the sp. gr. of the vap.; p_0 , the vap. press. of the liquid in the atm.; and p , the vap. press. of the evaporating liquid. The results are in harmony with those of R. Zsigmondy. The last-named found that when silica gel is immersed in a hydrosol of silver or ferric hydroxide, etc., it acts as an ultra-filter; water penetrates into the gel, and a layer of colloid is formed on its surface. E. M. Faber and H. G. Olson studied the repeated activation of the gel. T. Graham found that sulphuric acid can displace the water and form **silica sulphatogel**, if the hydrogel be first placed in dil. sulphuric acid (1:3), the product transferred to a stronger acid, and finally to conc. sulphuric acid.

H. N. Holmes and J. A. Anderson²¹ prepared mixed ferric oxide-silica gel by treating a soln. of sodium silicate with one of ferric chloride; and similar mixed gels were made with aluminium, chromium, calcium, copper, or nickel oxide in place of ferric oxide.

Organogels of silicic acid.—T. Graham²² prepared sols and gels of silica with fluids other than water—e.g. hydrochloric, nitric, sulphuric, formic, acetic, and tartaric acids, sugar-syrup, glycerol, benzene, carbon disulphide, alcohol, ether, and fixed oils. These liquids can displace more or less water without gelatinizing the dissolved silica. If alcohol be added to a hydrosol, containing not more than one per cent. of silica, and the water be removed by drying in vacuo over a desiccating agent; or if mixture of alcohol and silica hydrosol be dialyzed in a jar of alcohol, the water and a soln. of silica alcohol remain; it is **silica alcisol**. The alcisol is gelatinized by a slight increase in conc.; the liquid gives no evidence of the presence of a silicic ether. The corresponding **silicic alcogel** is also made by placing silicic hydrogel with 8–10 per cent. of silica, SiO_2 , in absolute alcohol, and changing the latter repeatedly until the water of the hydrogel is replaced by alcohol. The product contains 11.64 per cent. of alcohol. Silica alcogel passes into the hydrogel when placed in water, and compounds with other liquids—ether, benzene, carbon disulphide, etc.—miscible with alcohol—are obtained by placing the alcogel in the desired liquid. The ether of the **silica etherogel** can be replaced by fixed oils, by placing the gel in the required liquid. W. Kühne found that glycerol, like alcohol, displaces water from the hydrogel, forming **silica glycerogel**. S. P. Kramer studied the preparation of oil emulsions by the aid of silica gel. W. A. Patrick made silica gels impregnated with metallic oxides by mixing soln. of sodium silicate with a soln. of a metallic salt easily hydrolyzed—e.g. ferric chloride—after the gel had set, it was washed free from chlorides. B. S. Neuhausen and W. A. Patrick could not remove *all* the water from silicic acid gels by anhydrous alcohol, acetone, or benzene.

§ 22. The Silicates and the Aluminosilicates

A good formula indicates the convergence of knowledge; if it fulfils that purpose it is useful, even though it may be supplanted at some later date by an expression of still greater generality. Every formula should be a means towards this end, and the question whether it is assuredly final is of minor importance. Indeed, there is no formula in chemistry to-day of which we can be sure that the last word has been spoken.—F. W. CLARKE (1914).

Silicic acid at ordinary temp. is one of the feeblest of the inorganic acids. The acid is precipitated from aq. soln. of its alkali salts by carbon dioxide. Observations on the lowering of the f.p., and the electrical conductivities¹ of aq. soln. of the alkali silicates show that they are almost completely hydrolyzed: $\text{Na}_2\text{SiO}_3 + \text{H}_2\text{O} = 2\text{NaOH} + \text{SiO}_2\text{colloid}$, when the dilution is approximately 0.02 mol. per litre. The ready hydrolysis of the alkali silicates is in agreement with the difficulty which attends the preparation of the ammonium silicates—*vide infra*.

Although chemically inactive at ordinary temp., silica acts as a powerful acid anhydride at high temp., combining with the bases and many metallic oxides to form more or less fusible silicates. When silica is melted with sodium carbonate, carbon dioxide is expelled with effervescence. The reaction: $\text{Na}_2\text{CO}_3 + \text{SiO}_2 \rightleftharpoons \text{Na}_2\text{SiO}_3 + \text{CO}_2$, resembles the action of sulphur dioxide on the same salt at ordinary temp.: $\text{Na}_2\text{CO}_3 + \text{SO}_2 \rightleftharpoons \text{Na}_2\text{SO}_3 + \text{CO}_2$. When sodium silicate is dissolved in water it is decomposed by sulphuric acid, silicic acid is liberated: $\text{Na}_2\text{SiO}_3 + \text{H}_2\text{SO}_4 = \text{Na}_2\text{SO}_4 + \text{H}_2\text{SiO}_3$. The two compounds can be separated by dialysis. Sodium silicate thus behaves like other salts, and silica is therefore regarded as an acid anhydride, **silicic anhydride**, SiO_2 , in the same sense that sulphur dioxide, SO_2 , is sulphurous anhydride. The powerful acid character of silica at high temp. turns on the fact that most of the acid anhydrides— SO_3 , P_2O_5 ,

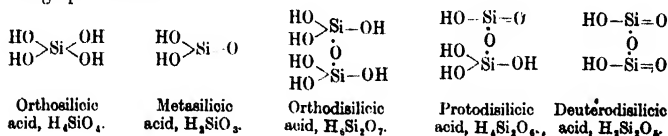

etc.—volatilize at much lower temp., and consequently, as soon as ever so little is displaced, the volatile anhydride passes away and ceases to compete with the silica for the base. At low temp. sulphur trioxide or carbon dioxide rapidly displaces silica from the bases when competing under equal conditions. The igneous rocks on the earth's crust contain silicates rather than carbonates, because at the high temp. of their formation, carbon dioxide could not compete successfully with the silica. Ever since that time, however, the weathering of these rocks has been proceeding slowly and continuously transforming the silicates into free silica, carbonates, and oxides or hydroxides.

Early in the nineteenth century, J. J. Berzelius,² J. W. Döbereiner, and J. Smithson expressed the idea that the silicate minerals are salts of silicic acid. A. Laurent proposed to represent the mineral silicates as salts of a series of imaginary silicic acids. The suggestion appeared more feasible after E. Frémy had established the existence of the related stannic acid in 1856; and the work of J. J. Ebelmen, C. Friedel, and J. M. Crafts, L. Troost and P. Hautefeuille, and A. Wurtz on the alkyl silicates, had shown the possible existence of a number of polysilicic acids and of *l'existence d'innombrables silicates que leur mode de génération est fondée, d'une part, sur le principe de l'accumulation des radicaux polyatomiques et de l'autre celui de la hydratation successive*. The subject was further developed by the work of T. S. Hunt, W. Odling, C. Weltzien, P. Groth, E. J. Chapman, F. W. Clarke, K. von Haushofer, C. Boedeker, L. Bombicci, P. Groth, G. Städeler, V. Wartha, A. Safarik, C. Simmonds, A. Streng, N. Lawroff, etc. Examples will be given in connection with the individual silicates. The silicates can be regarded as salts of silicic acid and its various condensation products. The general formula of all the silicic acids is $(n+m)H_2O.nSiO_2$, or $H_{2m}Si_nO_{2n+m}$, where n denotes the number of silicic atoms, and m , half of the hydrogen atoms per mol. The silicic acids can be named by starting from the *orthosilicic acids*, the acids formed by the loss of one mol of water per mol of acid can be called *protosilicic acids*, or, as is more usually the case, *metasilicic acids*; the loss of two mols of water gives *deuterosilicic acids* or *mesosilicic acids*; the loss of three mols of water gives the *triterosilicic acids* or *parasilicic acids*; the loss of four mols of water gives the *tettersilicic acids*, and the loss of five mols of water gives the *penterosilicic acids*. These acids are illustrated in Table X, which can be extended to the right and downwards if occasion should

TABLE X.—NOMENCLATURE OF THE SILICIC ACIDS AND SILICATES.

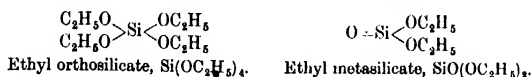

Type.	1 mono-	2 di-	3 tri-	4 tetra-	5 penta-
Ortho-	$H_{4n+3}Si_nO_{n+1}$	H_4SiO_4	$H_4Si_2O_7$	$H_4Si_3O_{10}$	$H_4Si_4O_{13}$
Meta-(proto-)	$H_{3n}Si_nO_{2n}$	H_3SiO_3	$(H_3Si_2O_6)$	$(H_3Si_3O_9)$	$(H_3Si_4O_{12})$
Meso-(deutero-)	$H_{2n-3}Si_nO_{3n-1}$	—	$H_2Si_2O_5$	$H_2Si_3O_8$	$H_2Si_4O_{11}$
Para-(tritero-)	$H_{2n-6}Si_nO_{3n-2}$	—	—	$H_2Si_3O_7$	$H_2Si_4O_{10}$
Tetterso-	$H_{2n-8}Si_nO_{3n-3}$	—	—	$H_2Si_4O_9$	$H_2Si_5O_{12}$
Penterso-	$H_{2n-11}Si_nO_{3n-4}$	—	—	—	$H_2Si_5O_{11}$

arise. Each member of a horizontal row differs from the one which precedes by the addition of H_2SiO_3 ; and each member of a vertical column differs from the one which precedes by the removal of H_2O . The various metasilicic acids are polymers of one another; and those formulæ enclosed by brackets in the table are polymers of some other member of the series. The following are illustrations of the graphic formulæ:

Formulæ for silicates like those of C. Simmonds, which represent the silicon atoms as being joined directly to one another, and not through intermediate oxygen atoms, are considered to be improbable, because, as R. Wegscheider has emphasized, (i) compounds with silicon atoms directly united are unstable reducing agents, and (ii) if the silicon atoms are directly united, oxygen atoms must also be directly united, and this again indicates an unstable oxidizing agent. The union of the strongly reducing group Si.Si with the strongly oxidizing group O.O gives extremely unstable combinations in marked contrast with the stable polysilicates.

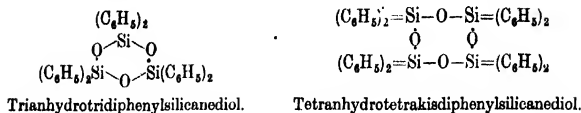

Although the existence of the ortho- and meta-silicic acids has not been definitely established, there is less doubt about the alkyl salts of orthosilicic acid, typified by ethyl orthosilicate, and ethyl metasilicate with the respective formulæ:

These compounds are formed by the action of the corresponding alcohols on silicon fluoroform, SiHF_3 . Thus, **methyl orthosilicate**, $\text{Si}(\text{OCH}_3)_4$, has a sp. gr. of 0.9676 (0°), and it boils at 165° ; **ethyl orthosilicate**, $\text{Si}(\text{OC}_2\text{H}_5)_4$, has a sp. gr. of 1.0589 (0°), and boils at 166° ; **propyl orthosilicate**, $\text{Si}(\text{OC}_3\text{H}_7)_4$, has a sp. gr. of 0.905 (0°), and boils at 522° ; and **amyl orthosilicate**, $\text{Si}(\text{OC}_5\text{H}_{11})_4$ has a sp. gr. of 0.870 (0°), and boils at 323° . Quite a large number of mixed alkyl orthosilicates have been prepared. **Ethyl metasilicate**, $\text{SiO}(\text{OC}_2\text{H}_5)_2$, boiling at about 360° , is said to have been prepared by J. J. Ebelmen³ in 1846, although there is some doubt whether or not Ebelmen's metasilicates are not really impure orthosilicates. L. Troost and P. Hautefeuille have made a polymer of the metasilicate, *viz.* $(\text{C}_2\text{H}_5)_2\text{SiO}_2$. Ethyl orthosilicate can be regarded as the terminal member of a series of derivatives.

	B.p.	Sp. gr. (0°)	Formula.
Tetra-ethylsilicon	152.5°	0.8341	$(\text{C}_2\text{H}_5)_4\text{Si}$
Tri-ethylsilicon ethylate	153°	0.8403	$(\text{C}_2\text{H}_5)_3\text{Si}(\text{OC}_2\text{H}_5)$
Di-ethylsilicon diethylate	155.8°	0.8752	$(\text{C}_2\text{H}_5)_2\text{Si}(\text{OC}_2\text{H}_5)_2$
Ethylsilicon triethylate	159.5°	0.9207	$(\text{C}_2\text{H}_5)\text{Si}(\text{OC}_2\text{H}_5)_3$
Silicon tetraethylate	165.5°	0.9676	$\text{Si}(\text{OC}_2\text{H}_5)_4$

If tri-ethylsilicon ethylate be treated with acetic anhydride, and the resulting acetic ether—**triethylsilicon acetate**, $(\text{C}_2\text{H}_5)_3\text{Si}(\text{OC}_2\text{H}_3\text{O})_2$ —be hydrolyzed with potash-lye, it yields **triethylsilicon hydroxide**, $(\text{C}_2\text{H}_5)_3\text{Si}(\text{OH})$, which has a constitutional analogy with the carbon derivative—triethyl carbinol, $(\text{C}_2\text{H}_5)_3\text{C.OH}$. Acetyl chloride converts diethylsilicon diethylate into **diethylsilicon dichloride**, $(\text{C}_2\text{H}_5)_2\text{SiCl}_2$, which boils at 148° , and is transformed by water into **diethylsilicon oxide**, $(\text{C}_2\text{H}_5)_2\text{SiO}$, which has a constitution analogous with diethyl ketone, $(\text{C}_2\text{H}_5)_2\text{CO}$. Ethylsilicon triethylate is transformed by acetyl chloride into a fuming liquid, **ethylsilicon trichloride**, $\text{C}_2\text{H}_5\text{SiCl}_3$, which boils at about 100° , and is transformed by water into **ethyl silicic acid**, $\text{C}_2\text{H}_5\text{SiO.OH}$, which is a white amorphous powder with a formal analogy to propionic acid, $\text{C}_2\text{H}_5\text{CO.OH}$, and is accordingly sometimes called *silicopropionic acid*, or *silicopropionic acid*, the corresponding **methylsilicic acid**, $\text{CH}_3\text{SiO.OH}$, is called *silico-acetic acid*, on account of its formal analogy with acetic acid, $\text{CH}_3\text{CO.OH}$. Silico-acetic acid has been made by the action of conc. hydriodic acid on methylsilicon triethylate, $\text{CH}_3\text{Si}(\text{OC}_2\text{H}_5)_3$. Similarly, **phenylsilicic acid**, $\text{C}_6\text{H}_5\text{SiO.OH}$, is called *silico-benzoic acid* on account of its formal analogy with benzoic acid, $\text{C}_6\text{H}_5\text{CO.OH}$; and **benzylsilicic acid**, $\text{C}_7\text{H}_7\text{SiO.OH}$, is called *silicotoluic acid* on account of the resemblance of its formula with toluic acid, $\text{C}_7\text{H}_7\text{CO.OH}$. These two compounds are formed during the hydrolysis of the trichlorides of phenylsilicon or tolylsilicon respectively. F. S. Kipping⁴ has made a number of acids and anhydrides of the silicic acids—*e.g.* **diphenylsilicanediol**, $(\text{C}_6\text{H}_5)_2\text{Si}(\text{OH})_2$; **anhydrosilicodiphenylsilicanediol**, $\text{H}(\text{C}_6\text{H}_5)_2\text{Si.O.Si}(\text{C}_6\text{H}_5)_2\text{OH}$; as well as the anhydrides and some derivatives with three and four atoms of silicon in closed rings:

The rings in these compounds appear to be opened by hydrolysis with an alcoholic soln. of potassium hydroxide. J. A. Meads and F. S. Kipping specially remarked that "no closed chain compound has yet been obtained which contains in its mol. more than four atoms of silicon, and four atoms of oxygen."

Suppose that two mols. of orthosilicic acid unite or condense with the elimination of one mol. of water, the sexivalent *orthosilicic acid*, $\text{H}_6\text{Si}_2\text{O}_7$, would be formed. Although the free acid is not known, several alkyl salts have been prepared. For example, C. Friedel and J. M. Crafts⁵ found **hexa-ethoxyorthosilicate**, $(\text{C}_2\text{H}_5\text{O})_3\text{Si}.\text{O}.\text{Si}(\text{OC}_2\text{H}_5)_3$, among the products of the action of aq. alcohol on silicon hexachloride, Si_2Cl_6 . The liquid of sp. gr. 1.0196 (0°), boils between 233° and 238° (760 mm.); the corresponding **hexamethoxyorthosilicate** has a sp. gr. 1.441 (0°), and boils between 201° and 202.5° . Lists of the compounds of silicic with organic radicles, and of other so-called organo-silicon compounds, will be found in the standard works on Organic Chemistry.

J. J. Berzelius⁶ classified the silicates according to the *oxygen ratio*, that is, the ratio of the number of oxygen atoms in the base to the number in the acid. Thus, the silicate, R_4SiO_4 , is regarded as a compound of $2\text{R}_2\text{O}.\text{SiO}_2$ with the oxygen ratio 1 : 1; $\text{R}_4\text{Si}_3\text{O}_8$, as $2\text{R}_2\text{O}.3\text{SiO}_2$, with the oxygen ratio 1 : 3; orthoclase, $\text{NaAlSi}_3\text{O}_8$, as $\text{Na}_2\text{O}.\text{Al}_2\text{O}_3.6\text{SiO}_2$, with the oxygen ratio 1 : 3. J. J. Berzelius here regarded the alumina as a base. F. W. Clarke also regarded aluminium as a trivalent base furnishing aluminium orthosilicate, $\text{Al}_4(\text{SiO}_4)_3$; and by various substitutions obtained formulæ corresponding with numerous mineral silicates. It is, however, well known that alumina is an amphoteric oxide, for it sometimes acts as an acid, and sometimes as a base. It is therefore probable that in some compounds alumina, together with silica, acts as a complex acid, and in other compounds it acts as a true base. Accordingly, a number of different views have been adopted as to the constitution of the aluminium silicates.

In 1869, C. F. Rammelsberg⁷ suggested that the aluminium silicates are really *double salts* of aluminium silicate and of a silicate whose basic element is stronger than aluminium. The two salts are united by a kind of residual affinity as is supposed to be the case with the alums. This view was adopted by D. A. Brauns, and V. Goldschmidt. They regarded leucite and beryl as compounds of R_4SiO_4 and $\text{Al}_2\text{Si}_3\text{O}_9$; nephelite and sodalite as compounds of R_4SiO_4 and $\text{Al}_2\text{Si}_3\text{O}_{12}$; and mica as a compound of $\text{R}_6\text{Si}_3\text{O}_9$ and $\text{Al}_2\text{Si}_5\text{O}_{12}$; etc.

Another set of hypotheses assumes that many aluminium silicates are *solid solutions* or *isomorphous mixtures* of silicates and aluminates. For example, G. Tschermak,⁸ E. Bauer, W. Vernadsky, and J. Morozewicz have elaborated theories that a very great number of silicates are not really so complex as is suggested by their empirical formulæ because they are really mixtures of two or more simpler silicates. This hypothesis has been applied to explain the structure of pyroxene, scapolite, mica, chlorite, etc. For instance, the scapolite minerals can all be regarded as mixtures of two terminal members, meionite, $\text{Al}_6\text{Ca}_4\text{Si}_6\text{O}_{25}$, and marialite, $\text{Al}_3\text{Na}_4\text{Si}_6\text{O}_{24}\text{Cl}$. It is probably true that many aluminium silicate minerals are isomorphous mixtures or solid soln. of two or more aluminium and other silicates.

From another point of view, the aluminosilicates can be regarded as *salts of basic radicles with complex alumino-silicic acids*, analogous to the complex silicotungstic or silicomolybdic acids of W. Gibbs.⁹ These complex aluminosilicates are no more closely related to the silicates proper than the ferrocyanides are related to the cyanides. The acidic character of some or all the alumina in the aluminosilicates

was indicated by P. A. von Bonsdorff,¹⁰ J. J. Berzelius, T. Scheerer, C. Bodecker, W. Odling, and D. A. Brauns. The idea was contested by V. Wartha. In illustration of the hypothesis that alumina may have acidic properties in the silicates, S. L. Penfield and H. W. Foote¹¹ suggested that the tourmalines and amphiboles are substitution products of tourmalinic and amphibolic acids where the hydrogen atoms of the hypothetical acids are replaced by different elements or radicles without change in crystalline form. W. Vernadsky and others have extended S. L. Penfield and H. W. Foote's idea that the **silicate minerals are salts of complex mineral acids** which are in many cases more complex than is indicated by the empirical formula. The aluminosilicate minerals are not regarded as salts of ortho-, meta-, or other silicic acids; nor as substitution products of normal aluminium silicate, but each group of minerals is regarded as comprising salts of particular aluminosilicic acids—*vide* heteropolyacids. Each group is characterized by a particular crystalline form, and considered to be capable of isomorphous substitutions. Just as it is convenient to refer the different silicates to more or less hypothetical silicic acids, so may it be convenient to refer compound silicates to hypothetical aluminosilicic acids:

	Examples.
Alumino-monosilicic acid, $\text{Al}_2\text{O}_3 \cdot \text{SiO}_2 \cdot n\text{H}_2\text{O}$	Angite.
Alumino-disilicic acid, $\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot n\text{H}_2\text{O}$	Kaolinite.
Alumino-trisilicic acid, $\text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2 \cdot n\text{H}_2\text{O}$	Natrolite.
Alumino-tetrasilicic acid, $\text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2 \cdot n\text{H}_2\text{O}$	Pyrophyllite.
Alumino-pentasilicic acid, $\text{Al}_2\text{O}_3 \cdot 5\text{SiO}_2 \cdot n\text{H}_2\text{O}$	Chabazite.
Alumino-hexasilicic acid, $\text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2 \cdot n\text{H}_2\text{O}$	Felspar.

The hypothetical acids are sometimes named after the leading minerals. The subject has been discussed by R. Scharizer, W. and D. Asch, K. Zulkowsky, R. Gans, T. Uffers, W. Pukall, W. Manchot, P. Erculisse, J. W. Mellor and A. D. Holdcroft, W. Stremme, etc. R. Schwarz and H. Bausch have prepared a cobaltic silico-aluminosilicate in which part of the silicate forms part of the complex anion, and part is present as cation. This fact is taken to support the aluminosilicate hypothesis. In his interesting memoir: *The Constitution of the Natural Silicates* (Washington, 1914), F. W. Clarke argued that the natural silicates have probably a simple structure: (i) because of the small number, a few hundred at the most—of the known silicates. If complexity were the rule, a far greater number might have been expected because of the diverse conditions under which the silicates have been formed in thousands of different localities. (ii) As a general rule, also, complex structures are characterized by instability, whereas the silicates as a class are exceedingly stable. Again, in deciding between the rival formulae, other things being equal, a symmetrical formula is preferable to an unsymmetrical formula because symmetry conduces to stability, and most of the silicates are very stable compounds.

This of course does not tell against the aluminosilicate hypothesis. The main difficulty in practice is to distinguish between aluminium as a base, and aluminium as part of the acid complex. Consequently, in the subsequent discussion of particular silicates it is generally assumed that the aluminium is a base until ripper knowledge enables a distinction to be made. There is, however, no particular difficulty in building up a system of aluminosilicates as consistent as that obtained by regarding aluminium as a trivalent base. J. Jakob, and P. Erculisse have applied A. Werner's system:

I.—Silicates with simple silicic acid ions:

(1) *Hexozysilicates*. E.g. *asperolite*, $\left[\text{SiO}_6\right]_{\text{H}_6}^{\text{Cu}} \left[\text{SiO}_6\right]_{\text{Al}}^{\text{Al}} \text{Fe}$.

(2) *Pentozysilicates*. E.g. *andalusite*, $\left[\text{SiO}_6\right]_{\text{Al}_5}$; *titanite*, $\left[\text{SiO}_6\right]_{\text{Ti}}^{\text{Ca}} (\text{Fe})$.

(3) *Tetrozysilicates*. E.g. *diopside*, $\left[\text{SiO}_6\right]_{\text{H}_4}^{\text{Ca}}$.

II.—Silicates with complex silicic acid ions :

- (1) *Monosilicohexosylsilicates*. *E.g.* *serpentine*, $\left[\text{SiO}_2, \text{SiO}_4 \right]_{\text{H}_2}^{\text{Mg}_2, \text{H}_2\text{O}}$.
- (2) *Disilicohexosylsilicates*. *E.g.* *meerchaum*, $\left[\text{SiO}_2, \text{SiO}_4 \right]_{\text{H}_4}^{\text{Mg}_2 + n\text{H}_2\text{O}}$.
- (3) *Trisilicohexosylsilicates*. *E.g.* *pyroxenes* and derivations like *talc*, $\left[\text{Si}(\text{SiO}_4)_3 \right]_{\text{H}_2}^{\text{Mg}_2}$.

III.—Silicato-salts :

- (1) *Tetroxysilicato-salts*. *E.g.* *nephelite*, $\left[\text{Al}(\text{SiO}_4)_3 \right]_{\text{Na}_3}^{\text{Al}_3}$.
- (2) *Pentoxysilicato-salts*. *E.g.* *sillimanite*, $[\text{Al}(\text{SiO}_4)_3]\text{Al}_5$.
- (3) *Hexoxysilicato-salts*. *E.g.* *dumortierite*, $[\text{SiO}_4]_4\text{Al}_6$.
- (4) *Trisilicotetroxysilicato-salts*. *E.g.* *leucite*, $\left[\text{Al}(\text{SiO}_4, \text{SiO}_2)_2 \right]_{\text{K}_3}^{\text{Al}_2(\text{Na})}$.
- (5) *Hexasilicotetraoxysilicato-salts*. *E.g.* *orthoclase*, $\left[\text{Al}(\text{SiO}_4, \text{SiO}_2, \text{SiO}_2)_3 \right]_{\text{K}_3}^{\text{Al}_3}$.
- (6) *Trisilicopentoxysilicato-salts*. *E.g.* *rasonite*, $\left[\text{Pb}(\text{SiO}_2, \text{SiO}_2)_3 \right]_{\text{CaCl}_2}^{\text{Pb}_2}$.
- (7) *Hexasilicopentoxysilicato-salts*. *E.g.* *pollur*, $\left[\text{Al}(\text{SiO}_4, \text{SiO}_2, \text{SiO}_2)_3 \right]_{\text{H}_2}^{\text{Al}_3}$.
- (8) *Trisilicohexoxysilicato-salts*. *E.g.* *olivine*, $[\text{Mg}(\text{SiO}_4, \text{SiO}_2, \text{SiO}_2)_2]\text{Mg}, \text{Fe}_{11}$.

IV.—Compounds of a higher order in which not an atom, but an atomic grouping appears as the nucleus. *E.g.* *tourmaline*.

Many types of these silicate compounds are able to crystallize both with and without water of crystallization. The association with water mols. is fundamentally a partial regeneration of complex hydrated ions. This renders possible subsequent dissociation on hydrolysis.

W. and D. Asch, in their work *Die Silicate in chemischer und technischer Beziehung* (Berlin, 1911), have invented an extraordinarily comprehensive hypothesis; they imagine that there are closed-ring polymers of silica, SiO_2 , and alumina, Al_2O_3 , arranged with five or six silicon or aluminium atoms alternating with oxygen atoms. Those rings with five atoms of silicon or aluminium are called *pentites*, and those with six, *hexites*. Using the hexites and pentites as bricks in the hands of a builder, the inventors of the hypothesis build up graphic formulæ in which the composition of any given silicate or aluminosilicate is finally represented as a multiple of the ordinary empirical formula. This mode of representing the constitution leads to many more types of complex silicates than nature has produced. If the imagination can proceed unrestrained by facts, an indefinite number of similar systems could be devised with an indefinite number of pairs of similar kinds of rings. For instance, in addition to the hexite-pentite hypothesis, it is open similarly to postulate an indefinite number of analogous hypotheses with pairs, 2-3, 3-4, 4-5 . . . of rings; *e.g.* if a silicate has the empirical formula $\text{MgO} \cdot \text{Al}_2\text{O}_3 \cdot \text{SiO}_2$, and the mol. weight is unknown, in the absence of proof to the contrary, it is open to postulate mol. wts., $(\text{MgO} \cdot \text{Al}_2\text{O}_3 \cdot \text{SiO}_2)_n$, where n has any desired integral value ranging upwards from unity. The inventors also represent by graphic formulæ glassy mixtures containing an indefinite number of fused silicates, and also impure silicates definitely known to be mechanical mixtures. F. W. Clarke rightly says of this system: "A generalization which does too much may be worse than no generalization at all."

These formulæ stand virtually on the same ground in illustrating our extreme ignorance of the mol. constitution of the silicates. Hypotheses are often multiplied with reckless abandon when the evidence is feeble and the facts are few. This has been the case with the formulæ of minerals. The hypotheses may serve a useful

purpose if they stimulate interest and work, but an inutile purpose if they hinder the exploration of other useful channels by a bigoted and intolerant attitude toward rival hypotheses. The insolubility and non-volatility of the silicates prevents a determination of their mol. wt.; and their general chemical stability offers a great obstacle to the study of their mol. constitution by the usual chemical methods. S. J. Thugutt,¹² J. Lemberg, F. W. Clarke and co-workers, G. Steiger, P. G. Silber, etc., have made a start on the substitution of radicles in the silicates; and on the fractional decomposition of these compounds—*vide* permutites and hydrated aluminium silicates. A. Damour, C. Boedeker, C. F. Rammelsberg, A. Laurent, A. Beutell and K. Blaschke, etc., have studied the nature of the water in some of the hydrates—*vide* zeolites. According to G. Tammann, the mol. sp. hts. of the silicates are additive, and therefore the molecules are independent, and at temp. far removed from their m.p., do not vibrate appreciably. Hence, only in the neighbourhood of the m.p. do isomorphous complex substances diffuse into one another visibly. In solution, silicates undergo hydrolysis, and their behaviour in a soln. therefore gives no definite information as to the molecules which exist in the solid. The complex silicates differ from the carbon compounds in that they are usually decomposed when dissolved or in the fused state, and the mol. theory of organic chemistry finds no application in the chemistry of silicates. As H. E. Boeke has shown, in a few cases determinations of surface tension, electrical conductivity, diffusion, and depression of f.p. have been employed to make an estimate of the mol. wt. The study of the space-lattice through the X-radiograms seems at the present time to hold alluring promises for the next advances of our knowledge of the constitution of the silicates. Although the existence of definite radicles are being recognized yet the condition of this branch of chemistry is very like that of the organic chemistry before Avogadro's hypothesis had been adopted as a guide. Such mol. formulæ as we have are at present of doubtful validity. After all has been said, the constitution of the silicates is not much in advance of A. Laurent's time, when he could say in his *Mémoire sur les silicates*:

We have a silicate that contains $\text{Si}_3\text{O}_5, \text{Mg}_{21}, \text{Al}_7, \text{H}_{30}$, and we discuss seriously whether the atoms have the arrangement $(11\text{SiO}_2, 21\text{MgO}) + 2(\text{SiO}_2, \text{Al}_2\text{O}_3) + 15\text{Aq.}$; or $7(\text{SiO}_2, 3\text{MgO}) + 2(3\text{SiO}_2, \text{Al}_2\text{O}_3) + 15\text{Aq.}$; or, $7(\text{SiO}_2, 3\text{MgO}, 2\text{H}_2\text{O}) + 2(3\text{SiO}_2, \text{Al}_2\text{O}_3) + \text{Aq.}$; or a hundred other similar formulae. What is there to prove that the silica is distributed into three principal groups; that the magnesia forms two distinct combinations; that the water occupies two different places? Does this split by its reactions split into magnesian silicate on the one hand, and an aluminomagnesian silicate on the other? I have often read the discussions that have taken place on this subject, and I avow that I have never found anything but what was arbitrary or according to routine; what I saw most clearly, was that, in general, the greatest regard was paid to authority. . . . We should arrive at results quite as satisfactorily by putting the atomic letters of a formula into an urn, and then taking them out, haphazard, to form dualistic groups.

Graphic methods for representing the composition of the silicate minerals have been discussed by E. S. Fedoroff,¹³ J. Stiny, J. F. Kemp, J. P. Iddings and co-workers, C. K. Leith and E. C. Harder, E. Steidtmann, W. J. Mead, W. Lindgren, F. L. Ransome, J. Stiny, W. Cross, L. V. Pirsson, H. S. Washington, W. H. Hobbs, L. C. Graton, A. Lacroix, W. C. Brögger, H. Rosenbusch, O. Mügge, A. Osann, F. Becke, A. Michel-Lévy, A. Harker, J. R. Dakyns and J. J. H. Teall, E. Royer, W. S. von Waltershausen, V. A. Eyles and J. B. Simpson, E. T. Wherry, etc.

The synthesis of minerals.—The purest of minerals nearly always contain foreign matters which were originally present in the medium in which the crystals were formed. Analysis may then fail to reveal the true composition of the mineral, and an artificial preparation may not distinguish between the essential and accidental constituents. The experiments which have been made on the synthesis of minerals have shown that many of them are definite chemical compounds, and have established numerous points of contact between the two sciences—chemistry and mineralogy.

The experiments are no less useful in enabling geologists to appreciate the conditions which prevailed during the formation of the different mineral species, although, as was emphasized by E. Frémy,¹⁴ nature sometimes works under conditions quite different from those which prevail in the laboratory. Still, as G. W. von Liebniz has said, *la nature n'est qu'un art plus en grand*. Indeed, H. B. de Saussure asked: *Ces lois générales du monde physique n'agissent-elles pas dans nos laboratoires de même que dans les souterrains des montagnes?* To-day, we realize that the answer must be: *Oui, certainement*. It has, however, not yet been found possible to synthesize some minerals; and it may be that it never will be possible to do so. This does not mean that the answer to the above question is in the negative. Take a simple case. A reaction may be so slow at ordinary temp. that an indefinitely large number of years is needed for the production of a particular compound. The reaction might be accelerated by raising the temp., but the products of the reaction might then be unstable and decompose. The synthesis of such a mineral could not be realized under practicable conditions.

The older researches of W. A. Lampadius,¹⁵ N. G. Sefström, P. Berthier, J. Percy, F. Leblanc, and C. Bischof; and the more recent work by C. S. B. Richardson, A. L. Day and E. S. Shepherd, H. O. Hofman, W. Mostowitsch, R. Akerman, O. Boudouard, P. Greth, H. Steffe, J. W. Cobb, and others show that the **temperature of formation of a silicate may be lower than the fusion temperature of the components**, provided they are finely ground, and intimately mixed. C. F. Plattner's observation to the contrary—the fusion of a silicate occurs at a lower temp. than that at which its components originally fuse when they enter into combination—is probably based on the use of mixtures neither finely ground nor intimately mixed; and without taking the time-factor into consideration.

Silicates have been formed by fusing a mixture of the basic oxide or salt with silica—e.g. the alkalis and alkaline earths, lead oxide, magnesium oxide, etc.; by the action of various bases on gaseous silicon halide, etc.; by the dissolution of silica gel in a salt soln., or by the treatment of a soln., of an alkali silicate with other salts whereby less soluble silicates are precipitated— $\text{CuSO}_4 + \text{Na}_2\text{SiO}_3 = \text{Na}_2\text{SO}_4 + \text{CuSiO}_3$. Silicates imitating natural minerals have been synthesized in numerous ways, for example: (1) By heating a mixture of the required constituents with boric oxide in, say, a porcelain kiln; the boric oxide is volatilized, and the crystalline mineral is obtained.¹⁶ (2) By heating a suitable mixture with alkali carbonate or by the fusion of the required base with a suitable borate or silicate. (3) By heating the oxide or a suitable salt with silicon halide—e.g. H. St. C. Deville's¹⁷ synthesis of zinc orthosilicate by heating zinc oxide in a tube in a current of silicon fluoride: $\text{SiF}_4 + 4\text{ZnO} = \text{Zn}_2\text{SiO}_4 + 2\text{ZnF}_2$ —the zinc fluoride volatilizes. (4) By heating the metal in a stream of water vap. and silicon halide—e.g. S. Meunier's synthesis of enstatite by heating magnesium in a current of water vap. and silicon chloride. (5) Silicates are often found well crystallized in furnace slags and similar products. (6) By heating soln. of alkali silicates, may be under press. with sodium aluminate, or some other metal salt. (7) A. C. Becquerel also obtained a number of crystalline silicates by electrocapillary action.¹⁸ Crystals of the lime-soda feldspars, baryta-soda feldspars, and anorthite have been obtained by fusing the corresponding mixture of silica, alumina, lime, and soda. The alkali feldspars are too viscid when fused to crystallize in this way. Crystals of both albite and orthoclase have been obtained by fusion along with tungstic acid, an alkali tungstate or phosphate, or an alkali fluoride. F. Fouqué and A. Michel-Lévy¹⁹ obtained barium, strontium, and lead anorthites, oligoclases, and labradorites by fusing together mixtures containing 2-4.5 mols of silica; one, of alumina; 0-0.625, of sodium carbonate; and 0.375-1.0, of lead, barium, or strontium oxide.

One great difficulty attending the synthesis of silicates is their tendency to form glasses when the constituents are fused together. Some of these glasses readily crystallize if slowly cooled, but not if rapidly cooled. The presence of certain substances in the molten magma may promote rapid crystallization. For instance,

a tungstate or vanadate promotes the separation of crystals of felspar when mixtures of alkali, silica, and alumina are fused together. Certain gases, too, favour crystallization—e.g. nitrogen gas favours the conversion of amorphous into crystalline zinc sulphide. H. St. C. Deville,²⁰ following E. de Beaumont, employed the term *agents minéralisateurs* or mineralizers for the substances which favour crystallization.

Je les caractérise par cette perpétuité de leur action qui se continue indéfiniment jusqu'à ce qu'elle soit fixée par les matières autres que celles sur lesquelles elles sont appelées à réagir pour ainsi dire par leur seule présence.

The *agents minéralisateurs* have also been called *cristallisateurs*, and *Krystallisation-agentien*. The most common mineralizing agents are the chlorides and fluorides of calcium, magnesium, alkalies, and silicon; the borates, phosphates, and tungstates of the alkalies or alkaline earths. Although in some cases the action of the mineralizing agent may be catalytic—whatever that may mean—this does not appear to be usually the case, for the addition may act by diminishing the viscosity or solvent action of the magma, or by lowering the temp. limits of its stability. For example, calcium metasilicate separates above 1200° in hexagonal crystals, but, in the presence of calcium fluoride or sodium borate, monoclinic wollastonite separates at a temp. 200°–300° lower. Again, in P. Hautefeuille's²¹ experiments on the formation of quartz by heating silica with lithium molybdate below 900°; without lithium molybdate a temp. exceeding 900° is necessary for the crystallization, and tridymite is formed. P. Hautefeuille also synthesized other silicates in presence of tungstates or vanadates, e.g. with a mixture of silica, alumina, and potassium tungstate, orthoclase was obtained; and leucite if the alumina be in excess; with lithium tungstate, petalite was formed; and with ferric-oxide, potassium hydroxide, and silica ferri-leucite was produced. Other substances may retard crystallization—alumina, for instance, as shown by J. Pelouze,²² L. Appert, G. Bontemps, and J. H. L. Vogt, promotes the formation of glasses, and retards devitrification.

Other examples of the different syntheses are indicated in connection with specific minerals. The more important monographs on the subject are:

§ 23. The Alkali and Ammonium Silicates—Water-glass

In the first century of our era, Pliny¹ described the preparation of a glass by fusing together a mixture of white sand with three parts of nitre. G. B. Porta likewise prepared a glass by fusing rock crystal and cream of tartar; and G. Agricola, by fusing flint and cream of tartar. J. B. von Helmont said that this glass deliquesces when kept in a damp place. He added:

If stones, gems, sand, marble, flint, etc., be boiled in alkali-lye, they will dissolve, and the liquid when treated by acids, will yield a dust (precipitate) equal in weight, to that of the original mineral used.

J. R. Glauber called the soln. of flint in alkali-lye *liquor silicum* or *oleum silicum*—oil or liquor of flints, sand, or crystal—and added:

Take one part of white quartz or sand, mix it with three or four parts of salt of tartar or any other alkali, and put the mixture into a crucible so as not to fill more than one-third of it; since otherwise, in melting, the mixture would rise and flow out of the crucible. Let it stand in the fire half an hour that it may be well ignited and changed to a pellucid glass. Pour it out, and dissolve in water or better in lye; and the sand or silica will be dissolved, and changed into a thick water. The transparent clear glass is nothing but the most fixed parts of the salt of tartar and of flint united by heat, and turned to a soluble glass wherein lies hidden a great heat and fire. So long as it is kept dry from the air,

it cannot be perceived in it; but if you pour water on it, then its secret heat will discover itself. If you make it into fine powder in a warm mortar, and lay it in a moist air, it will dissolve and melt into a thick fat oil, and leave some faces behind.

J. N. von Fuchs, in 1818, made *soluble soda-glass* by fusing a mixture of 150 parts of white sand, 100 of soda ash, and 3 of charcoal in a reverberatory furnace, and extracting the cold glassy mass with water. The aq. soln. was evaporated to dryness and fused to form what he called *Natronwasserglas*; with potassium carbonate, in place of sodium carbonate, *Kaliwasserglas* results. Many other proportions have been recommended by P. Ebell,² A. Mitscherlich,*J. M. Ordway, J. von Liebig, G. Forchhammer, D. A. Péniaffoff, H. Propfe, B. von Ammon, H. V. Regnault, L. A. Buchner, H. Fleck, etc. Commercial *water-glass* is made by J. N. von Fuchs's process, and the glassy mass is extracted with water in an autoclave. J. M. Ordway used sodium sulphate as the source of the alkali. If alumina, lime, or magnesia are present, the product will not be soluble. The attempt to make hydrogen chloride and sodium silicate by the action of steam on a mixture of sodium chloride and silica—discussed by R. A. Tilghman, W. Gossage, R. Lieber, H. Grüneberg and J. Vorster, H. H. Lake, C. F. Claus, and A. Ungerer—has not been successful (2. 20, 28). K. Schliephacke and H. Riemann fused felspar or a silicate rock—*e.g.* granite—with raw carnallite, and extracted the mass with water. Water-glass is also made by wet processes. For example, J. N. von Fuchs dissolved freshly precipitated silicic acid in an aq. soln. of the alkali hydroxide. Soln. of alkali silicate with a definite ratio of base to silica were made in this way by J. M. van Bemmelen, F. Mylius and F. Förster, R. Lüpke, L. Kahlenberg and A. T. Lincoln, etc. Commercially, water-glass is made in the wet way by dissolving powdered flint, quartz, or kieselguhr in a soln. of sodium hydroxide of sp. gr. 1.22–1.24 under 3–4 atm. press. in an autoclave for about 3 hrs. E. Kleinschmidt and F. Steinberg recommended calcined kieselguhr. The soln. is heated by blowing in steam; and the liquor is finally evaporated in iron pans to a sp. gr., say, 1.7. If the water-glass contains more silica than corresponds approximately with $\text{Na}_2\text{O} \cdot 3\text{SiO}_2$, the excess of silica for water-glass is particularly liable to separate from the soln. The use of kieselguhr as a source of silica has been discussed by J. von Liebig, J. M. Ordway, A. Scheurer-Kestner, and R. Meyer. J. W. Hinchley discussed the preparation of sodium silicate from the leucite residues left after the removal of potash and alumina. To convert the liquid into the solid form E. A. Paterson recommended warming it at 60° under reduced press. until the water-content is 30 per cent. The solid product is ground to a fine powder and dried until the water-content is 12 per cent. The resulting dry powder is readily soluble in water.

According to J. N. von Fuchs, and J. M. Ordway, water-glass in 10 per cent. soln. is purified by treating it with one-tenth its weight of alcohol whereby the earths and metal oxide impurities are precipitated; after standing a few hours, one part of the filtrate is treated with two parts of alcohol when most of the sodium silicate is precipitated. This can be dried on absorbent paper, dissolved in four times its weight of water, and the alcoholic treatment repeated—3 or 4 times if necessary. A. Liebig had previously recommended the alcohol process for purifying water-glass. E. Jordis recommended digesting the soln. of water-glass at 50° for some time, when the flecks which separate contain most of the impurities.

The manufacture and properties of water-glass have been specially discussed by E. Kopp, A. A. Perazzo, O. Maetz, G. Deguide, W. H. Stanton, L. Schneider, J. M. Ordway, H. Zwick, J. W. Hinchley, L. Bernhard, H. Krätzer and L. E. Andés, M. Lenglen, F. Capitaine, F. C. Kuhlmann, F. Ransome, L. W. Codd, C. Bergeat, W. H. Dickerson, L. Schneider, W. H. Stanton, etc. According to F. J. Phillips, to obtain a soluble alkali silicate of high silica content, the product obtained by the fusion of alkali and silica is dissolved in water and an acid then added. Gelatinous silicic acid is precipitated. This precipitate by continued agitation is made to re-dissolve. The acid, preferably sulphuric acid, may be added in the form of spray, and after the subsequent agitation

or grinding, the soln. may be evaporated to dryness. To increase the fusibility of the alkali and silica, a little borax has been employed. I. P. Lihme evaporated the soln. by bringing a heated cylinder in contact with the soln. of water-glass in vacuo, and so obtained the dry product which could easily be broken up into fine flakes soluble in water; and W. Clayton and H. W. Richards sprayed the soln. into the top of a tower where hot air was introduced at 110° ; the exit gases at the bottom passed through bag filters to collect the powdered silicate. A solid soluble glass is made by grinding the ordinary insoluble glass either dry (R. M. Caven) or wet (J. W. Spensley and co-workers), and heating the product mixed with a little water, until a vitreous solid is obtained which dissolves readily and completely even in cold water.

The composition of some commercial grades is shown in Table XI. Many other

TABLE XI.—COMPOSITION OF SOME COMMERCIAL GRADES OF WATER-GLASS.

Sp. gr.	Molecular ratio: $\frac{\text{SiO}_2}{\text{Na}_2\text{O}}$	Weight ratio: $\frac{\text{SiO}_2}{\text{Na}_2\text{O}}$	Per cent. solid in soln.
1.235	4.2	4.06	26.8
1.325	3.8	3.68	33.4
1.375	3.0	2.92	35.5
1.39	3.3	3.21	38.4
1.42	3.3	3.21	40.0
1.5	2.9	2.82	44.5
1.56	2.5	2.38	46.7
1.6	2.0	1.95	48.7
1.7	2.0	1.95	54.5

grades are available for special purposes. In addition to these soln., silicate of soda can also be obtained in the form of lump glass, which can be dissolved in press. dissolvers at high temp., and also in the form of white powders which can be easily dissolved in hot water. These powders usually contain 15 to 20 per cent. of water and 85% to 80 per cent. of solid sodium silicate. In order to prepare water-glasses with a high silica content, F. J. Phillips and E. J. Rose dissolved precipitated silica in a soln. of water-glass.

The properties of water-glass.—After a soln. of water-glass had been exposed to the atm. two days, H. Ditz detected nitrous acid in the soln., and the amount increased as time went on. No hydrogen dioxide could be detected by means of titanous acid. When a three months old soln. is acidified with hydrochloric acid, carbon dioxide is evolved, and there is an odour resembling chlorine, though none can be detected. The chlorine found by E. Jordis may have been due to the action of decomposition products of nitrous acid on hydrochloric acid in presence of ferric and manganese compounds. Fused water-glass is dissolved by cold water very slowly, and even with boiling water the process is slow, and it proceeds so uniformly that the bits retain to the last their original form, except for a rounding of the sharp angles. If the proportion of silica be greater than that of a disilicate, the process of dissolution is tardy, and this the more the greater the proportion of silica. F. Mylius and F. Förster said that water-glass is decomposed by water into free alkali and silicic acid, a certain proportion of the latter becoming hydrated and dissolved. The soda water-glasses dissolve rather more slowly than the potash water-glasses. The monosilicates are comparatively quickly dissolved. W. Pukall said that soda and potash glasses are about equally soluble in water, and the solubility of each falls with increasing silica content. The solubility is greatly impeded if earth impurities be present, so that sands containing mica, felspar, lime, clay, iron oxide, etc., are not suited for making water-glasses. When a water-glass containing the impurities is treated with boiling water, earths and metal oxides may be left

an insoluble sediment. Some foreign matters may be dissolved because a soln. of water-glass can dissolve traces of most oxides, and the solvent power increases with the conc. of the soln. Hence, a soln. which is slightly turbid when dil. becomes clear by conc.—and conversely. P. A. Bolley, indeed, found that even the oxides of calcium, barium, and magnesium are slightly soluble in water-glass liquor. Dry water-glass coloured with manganese oxide is pink or violet, and, as F. C. Kuhlmann showed, it furnishes a pink or brown soln. A conc. soln. of water-glass is syrupy; and, when boiled, or exposed to air, it becomes covered with a tough skin which disappears when thrust beneath the surface of the liquid. The general properties of water-glass were discussed by J. G. Vail. A. H. Steele and J. W. Mellor found a sample of soda water-glass with 16.1 per cent. of alkali, calculated as soda, 35.6 per cent. of silica, and 48.3 per cent. of water, or 51.7 per cent. of $\text{Na}_2\text{O} : 2.3\text{SiO}_2$, had a sp. gr. 1.71:

Per cent. $\text{Na}_2\text{O} : 2.3\text{SiO}_2$	51.71	48.61	41.35	35.89	24.45
Sp. gr.	1.71	1.64	1.52	1.44	1.28

The liquor known in commerce as water-glass is a colloidal soln. of silica in a soln. of sodium silicate; the ratio $\text{Na}_2\text{O} : \text{SiO}_2$ varies molecularly from 1 : 1.5 to 1 : 4. The possible "dry contents" of a soln. increases greatly as the proportion of silica decreases, and at the same time, the viscosity of the liquid at a given sp. gr. decreases. Thus, according to R. Furness, with two soln. having the ratios 1 : 1.5 and 1 : 4, the former is a thin liquid easily poured, while the latter is jelly-like and stiff. He gave for the viscosity in C.G.S. units at 20°:

Sp. gr.	1.4250	1.4385	1.3580	1.3598
Ratio $\text{Na}_2\text{O} : \text{SiO}_2$	1 : 3.26	1 : 3.16	1 : 3.53	1 : 3.48
Viscosity	21.9	10.8	3.1	1.7

J. D. Malcolmson found that the vol. of adhesive water-glass could be increased 25 per cent. without impairing the viscosity and other desirable qualities by the addition of urine. After the liquid has been evaporated at a high temp., the water-glass is malleable and very tenacious; and it may be drawn into threads like melted glass. It dries to a varnish of stony hardness when spread in a thin layer, but it does not part with its water except as the alkali is carbonated. J. F. Spencer and K. Proud obtained orthosilicic acid at the anode by the electrolysis of a 50 per cent. soln. of sodium silicate. The cathode was a platinum dish, and the anode a coil of platinum wire in a porous cell.

J. N. von Fuchs found that air-dried water-glass retained 12 per cent. of water; and J. M. Ordway found that a layer 0.25 in. thick retained 29 per cent. of water after being kept in a dry atm. for 2 years. The cake was then capable of bending under a steady press. The last portion of water was expelled only at a red heat. The affinity of water-glass for water is shown by the generation of heat observed by F. Mylius and F. Förster when the two substances are mixed. Fifty grammes of pulverized potash water-glass, $\text{K}_2\text{O} \cdot 3\text{SiO}_2$, were well mixed with enough water to form a thick pulp, which was left to itself at 18°. In a quarter of an hour the temp. had risen to 32°, and it remained at about this temp. for a long time. When the same glass, mixed with a little water, was warmed on a water-bath at 55°, the temp. of the mixture rose in a few minutes to 80°; and in about ten minutes the pulp had solidified into a homogeneous mass. This property accounts for water-glass setting like hydraulic cement, under water. The pulp formed by the swelling-up which occurs when it absorbs water, cements together the as yet unhydrated particles of the powder. In a day or two it becomes a glassy mass, of the hardness of stone, containing up to 50 per cent. of water. When heated, it gives out this water with violent tumescence; and at a red heat it acquires the character of alumina. Soda water-glass combines with cold water much more slowly. When reduced to powder, and kept under water, it takes two or three months to harden.

W. Morey represented his observations on the effect of press.—i.e. the amount

SILICON

of water added—on the solubility of water in water-glass by Fig. 55. According to W. Stericker, soln. of sodium silicate are shown by the ultra-microscope to be two-phase systems, and the disperse phase is negatively charged.

He said that when, say, 2 grms. of anhydrous glass of the composition $K_2O : SiO_2$ is heated with 1.5 c.c. of water, the cooled product is a hard homogeneous **hydrated glass** containing 8.25 per cent. of water. The amount of water retained by the glass depends on the temp., and increases as the proportion of water initially employed is increased, in general accord with Henry's law. As the water-content of the glass increases above 25 per cent. the product passes gradually, and continuously, from a hard, brittle glass to a very stiff paste, and finally to a very viscous soln. resembling ordinary water-glass. This is a striking illustration of the fact that a glass is merely a supercooled liquid. Similar hydrated glasses were obtained by A. I. Walcker, J. N. von Fuchs, J. M. Ordway, etc., by evaporating aq. soln. of water-glass; for they noted that the last portions of water are expelled only at a temp. approaching redness. The hard glasses were liquid at the temp. of their formation so that liquid soln. containing water and alkali silicate, may exist in equilibrium with solid and vapour up to 500°. It should also be pointed out that these hydrated glasses, liquid at the temp. of the experiment, may be regarded as fused mixtures, for the m.p. of the alkali silicate is greatly lowered by the addition of water. For example, $K_2Si_2O_5$ melts at about 1015°, but addition of about 8 per cent. of H_2O lowers its m.p. to about 500°. J. N. von Fuchs, A. I. Walcker, J. M. Ordway, C. Barus, etc., noted the swelling of hydrated glasses when heated; and G. W. Morey said that if a fragment of the clear, homogeneous, hydrated glass, the size of a pea, is contained in a 30 c.c. crucible, and heated over a flame, the substance swells enormously, often overflowing the crucible; the swelling continues until most of the water has been driven off. The spongy or pumiceous mass is composed of vesicles of the alkali silicate glass, often with walls thin enough to show interference colours.

In 1775, J. C. F. Meyer observed that *liquor silicium* diluted with a certain amount of water may be mixed with acids without precipitation; and he assumed that silica is either soluble in these acids or else is transformed into another earth. T. Bergman showed that the silica is precipitated if the soln. be not too dil.; and when the soln. is dil., he said that the particles of silica are so finely subdivided that they remain suspended in the liquid. When a dil. acid is added to a dil. soln. of sodium silicate, there is no immediate precipitation of silica, but after some time the whole liquid gelatinizes. The coagulation is faster with sulphuric acid than it is with hydrochloric acid; with the latter, the change may be delayed a long time, and the mixture may even be heated and partially evaporated without coagulation. According to T. Bergman, if acid be added sufficient just to neutralize the alkalinity of potash water-glass, the liquor remains clear, but it becomes turbid when boiled. According to J. Dalton, the addition of an acid, not sufficient for neutralization, precipitates a compound of alkali and silica, but with more acid, silica is precipitated as a gelatinous hydrate, some silica is left in soln., and this the more the greater the degree of dilution, and the less the acid employed. According to L. Doveri, an excess of acid added drop by drop to a soln. of potash water-glass of sp. gr. 1.200-1.332, precipitates 0.9 part of the silicic acid; with a soln. of sp. gr. 1.069, 0.4 part of the silicic acid is precipitated; and with a soln. of sp. gr. 1.029, the silica remains in soln.; but if the acid be added at once, and not in drops, or if the silicate liquor be added to the acid, no precipitation occurs even with conc. soln. The addition of potassium chloride to a silicate soln. of sp. gr. 1.043 renders it incapable of being precipitated by hydrochloric acid. He said:

"The silica appears to combine with the acid at the moment of liberation, for on

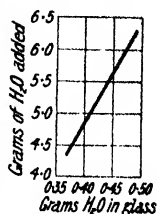

FIG. 55.—The Effect of Pressure (amount of added water) on the Solubility of Water in Water-glass at 420°.

neutralizing the acid with a soln. of potassium hydroxide added drop by drop, the whole of the silica is precipitated." According to C. J. B. Karsten, if a dil. silicate liquor be supersaturated with sulphuric, hydrochloric, nitric, or acetic acid, it remains clear even after long standing or exposure to heat, or when potassium nitrate or other salts are dissolved in it; and it is only by evaporation that the gelatinous silica is obtained. A. I. Walcker said that a soln. of soda water-glass diluted so as to contain 0.025-0.10 part of silica immediately gelatinizes when neutralized by an acid; with 0.01-0.02 part of silica, it does not form a jelly until after the elapse of 12 hrs.; and with 0.002 part of silica, no gelatinization occurs. J. von Liebig, O. Maschke, H. Rose, W. Lange, E. Ludwig, E. Jordis, C. Friedheim and A. Pinagel, etc., have made observations on this subject.

According to A. Hantzsch, F. Kohlrausch, and E. Jordis, an aq. soln. of alkali silicate has an alkaline reaction whatever be the proportion of acid to base. The hydrolysis of aq. soln. of alkali silicates is discussed below. According to E. Jordis, soln. of water-glass, freed from carbon dioxide, can be accurately titrated by acids with phenolphthalein as indicator, but with technical soln., the phenolphthalein fails more and more as the soln. is diluted, while the titration with methyl orange as indicator remains exact. F. Mylius and E. Groschuff found that the neutral point with hydrochloric acid using methyl orange as indicator varies with temp. and conc. W. Ludewig found that with increasing dilution, the amount of normal acid required for neutralization increases if methyl orange is used as indicator, and decreases if phenolphthalein is employed. Methyl orange gave the best results.

A dil. soln. of water-glass absorbs carbon dioxide from the atm.; but a conc. soln. scarcely absorbs any of that gas, and it is decomposed by a stream of carbon dioxide and gelatinized. Similar results are obtained when the soln. is treated with hydrocarbonates. According to F. C. Kuhlmann, when a soln. of water-glass is exposed to air, in about a fortnight it is converted into a transparent jelly which gradually shrinks, and in a few months is hard enough to scratch glass. C. J. B. Karsten found that if a dil. soln. of silica be supersaturated with hydrochloric acid, and then mixed in a closed vessel with enough ammonium carbonate to neutralize the hydrochloric acid, so that carbon dioxide is liberated in the liquid, the silica remains in soln., but separates on exposing the liquor to air, or on heating the liquor so as to drive the carbon dioxide from the soln. He therefore infers that the dissolved gas helps to keep the silicic acid in soln.; but this conclusion does not agree with other observations. The action of carbon dioxide and of alkali hydrocarbonates has been studied by L. Doveri, G. Lunge and W. Lohöfer, and E. Jordis. A conc. soln. of water-glass in the cold, or a boiling dil. soln., was found by L. Doveri to be coagulated by boric acid, sulphurous acid, tartaric acid, and by citric acid. F. A. Flückiger found that a soln. of water-glass is coagulated by chlorine, and bromine, but not by iodine.

When a few drops of dil. soln. of a metallic salt are added to water-glass, the precipitate first formed will generally disappear when the mixture is agitated. Consequently, liquor silicum may dissolve appreciable amounts of oxides of iron, zinc, manganese, tin, lead, copper, and mercury. Water-glass sat. with a zinc salt deposits a zinc salt when allowed to stand for a little while, and it may coagulate into a gelatinous mass; sodium zincate gives no change at first, but a precipitate soon forms. A highly alkaline sodium stannate may produce no change, but J. M. Ordway showed that with the normal alkali stannate, gelatinization may occur in a few hours or days. Alkali aluminates or beryllates also cause precipitation very quickly; while alkali manganates or chromates produce no alteration. Finely-divided lead monoxide coagulates the liquor, while the anhydrous oxides of zinc, mercury, and copper, or the hydroxides of iron, aluminium, and chromium, slowly change into silicates. Most metallic salts react with the liquor producing the colloidal metal silicate accompanied by a thickening of the whole mass. H. Ota and M. Noda obtained colloidal silicates by adding dil. soln. of water-glass to dil. soln. of salts of copper, silver, magnesium, zinc, aluminium, titanium, manganese,

iron (ous), and cobalt; and he studied the indophenol reaction with the products.

The formation of metallic silicates is well illustrated by a familiar experiment—*silica garden*: a litre beaker is filled with a soln. of sodium silicate (sp. gr. 1.1) and crystals of, say, cobalt nitrate, cadmium nitrate, copper sulphate, ferrous sulphate, nickel sulphate, manganese sulphate, zinc sulphate, etc., are allowed to fall into the beaker so as to rest on different parts of the bottom. The whole is allowed to stand overnight in a quiet place, when plant-like shoots are obtained which have a form and colour characteristic of each metal. R. Böttger, R. Dollfus, and G. J. Mulder discussed the nature of the silica trees.

B. von Ammon said that the precipitates obtained with metallic salts are usually metal silicates, and, in some cases, double silicates. L. Doveri found that copper and ferrous sulphates, lead acetate, and silver nitrate precipitate mixtures of the metal silicate and hydroxide, and silicic acid. The action of ferric hydroxide at 100° resulting in the formation of a silicate was studied by J. Lember, C. G. C. Bischof, and A. Daubrée. According to B. Bornträger, crystalline silicates can be produced by adding to a dil. soln. of water-glass, 10 per cent. soln. of the salts of calcium, barium, aluminium, chromium, iron (ie) nickel, cobalt, manganese, zinc, uranium, copper, and tin. W. Hennis studied the reaction with ferric chloride, and ferrous and cupric sulphates. F. Uffers studied the reactions of water-glass with metal hydroxides and salts; and R. Eberhard, the effect of a little chromic acid on the precipitated silicates. A. H. Erdenbrecher found that the precipitates produced by zinc salts and sodium silicate soln. in the presence of hydrogen dioxide, contain amounts of oxygen varying with the conc. of the hydrogen dioxide. The products are not definite compounds, but rather mixtures of zinc dioxide, zinc silicate, and silicic acid.

According to J. M. Ordway, barium carbonate and sulphate, and calcium fluoride, have no appreciable action. L. B. G. de Morveau, C. F. Bucholz, and J. W. Döbereiner said that baryta, strontia, or lime-water, or a soln. of potassium aluminate or calcium sulphate, precipitate all the silica from a soln. of potash water-glass. The silica is combined with the alkaline earth and part of the potassium. Most calcium salts are particularly energetic in their action; calcium carbonate acts very slowly, but when boiled there is flocculation. Magnesium, zinc, lead, and manganese carbonates give an immediate coagulation; and ammonium carbonate or alkali hydrocarbonates cause an instantaneous thickening with conc. soln. Ammonium salts precipitate silica. F. A. Flückiger said that aqua ammonia of sp. gr. 0.921 gelatinizes a soln. of water-glass of sp. gr. 1.392, and that when warmed in a closed vessel, the precipitate dissolves. If the ammonia soln. is one-tenth of the vol. of the soda water-glass liquor, no precipitation occurs; if one-fifth the vol., the precipitate which is formed redissolves at 90°, and reappears on cooling; and if one-sixth to one-eighth the vol., the precipitate clears at 30°. W. Heintz said that the precipitate is unchanged sodium silicate. J. von Liebig said that if a soln. of water-glass is dil. enough to give no precipitation with acids, a drop of ammonium carbonate or chloride produces an opalescence. F. A. Flückiger found that a 0.5 per cent. soln. of water-glass is precipitated by ammonium nitrate, and scarcely affected by ammonium chloride. J. Persoz, F. A. Flückiger, J. M. Ordway, W. Heintz, F. Mylius, etc., found that a highly siliceous water-glass liquor gives precipitates with alkali carbonates, acetates, tartrates, phosphates, borates, nitrates, sulphates, and chlorides; but the bisilicate soln., and others still more alkaline, are not affected by alkali carbonates, tartrates, nitrates, or sulphates. J. N. von Fuchs said that "alkali salts, particularly the carbonates and chlorides, give pasty precipitates when added to a soln. of water-glass." J. M. Ordway said that the normal carbonates are not particularly active as precipitants, but the hydrocarbonates behave as described by J. N. von Fuchs. Sodium chloride, said F. C. Kuhlmann, combines directly with sodium silicate, forming an insoluble compound, and the adherent sodium chloride soln. can be

removed by press. The reaction was also studied by F. Mylius. J. M. Ordway found that the alkali salts precipitate from water-glass liquor an uncombined silicate. W. Hennis said that the precipitations are not chemical reactions, but rather indicate the flocculation of colloid sols. The alkali acetates were found to be rather more efficient flocculants than the chlorides in precipitating water-glass. *Sodium arsenate*, or *phosphate*, gelatinizes the liquor owing to the acidity of these salts, and in this respect they resemble the hydrosulphates or hydrocarbonates. J. N. von Fuchs found that when *aluminium phosphate*, or *lead phosphate*, *sulphate*, or *carbonate*, is rubbed up with a soln. of water-glass, a tenacious mass is formed which, when exposed to air, sets as hard as stone. J. H. Johnson observed no precipitation of silica from a soln. of water-glass, containing some potassium cyanide, when in contact with *quartz*, powdered *pyrites*, granulated *lead*, or *zinc shavings*; but alkali zincate was formed when in contact with lead-coated zinc, *i.e.*, a *zinc-lead couple*. J. Errera found the *copper anode*, is attacked during the electrolysis of alkali silicate soln.

J. N. von Fuchs found that *ethyl alcohol* precipitates potash water-glass without change in composition from its aq. soln., and the supernatant liquor retains undecomposed alkali carbonate, sulphide, and chloride. He based a method of purifying water-glass on this observation. G. Forchhammer said that the alcohol-precipitation and washing removed from water-glass a part of the alkali, and that this separation continued until an octosilicate remained, $K_2O \cdot 8SiO_2$. J. M. Ordway added that water-glasses, containing less silica than $K_2O : 1.7SiO_2$, furnish a precipitate which is liquid; and those with more silica yield solids of greater and greater "firmness" as the relative proportion of silica is increased; but all these hard products belong to the same class of viscous solids as pitch. The more any given soln. of water-glass is diluted before adding alcohol, the greater the relative amount of silica in the precipitate. By mere precipitation under varied conditions, an indefinite number of differently constituted silicates may be obtained. While the ratio of base to acid can be infinitely diversified, the quantity of water generally amounts to not far from 50 per cent. The action of alcohol was also studied by A. Lielegg, G. Forchhammer, E. Frémy, T. Scheerer, and F. Mylius. J. M. Ordway found *methyl alcohol* and *acetone* also give precipitates with soln. of water-glass. Several organic compounds were found by F. A. Flückiger to coagulate water-glass soln.—*e.g.* *phenol*, *creosote*, *chloral hydrate*, *egg-albumen*, and *glue*. No precipitation occurred with *arabic acid*, *sugar*, *dextrine*, *glycerol*, *alkali resins*, etc. S. P. Kramer found that *animal or vegetable oils* added to a dil. soln. of water-glass (1 : 500) produce a fine and stable emulsion. The fatty acid of the oil forms with the sodium hydroxide, and the liberated colloidal silicic acid acts as a protective colloid.

The uses of water-glass.—The various applications of water-glass, said J. M. Ordway,³ turn on its adhesiveness in the hydrated state; its vitrifying power in the dry state; its alkaline nature; its capability of yielding soluble silica; and its peculiar chemical relations as a whole. He discussed the use of water-glass soln. as an adhesive—a kind of *mineral glue*—as a colourless cement for glass, porcelain, and stone, and as a medium for fixing paper-labels on glass. The setting qualities can be controlled by the manufacturer, and R. Furness showed that a soln. of water-glass possesses all the essential qualities of an efficient adhesive: (i) the ease, suitability, flexibility, and general efficiency of application to the materials to be united, and (ii) its power of setting in a suitable manner and time with the formation of a bond of the desired strength. He concluded:

Sodium silicate soln. are superior to animal and vegetable adhesives in that they are fire-resisting, do not become rancid, and are vermin-repellent. Silicate adhesives are quite odourless, and produce damp-proof articles: they have a relatively high bond strength, and their setting times can be varied over a wide range. They are ever-ready, requiring no heat before or during application, and they give consistent results.

According to J. D. Malcolmson, on adding an electrolyte to water-glass the

colloidal silica is coagulated, but if the soln. is stirred during the addition, and for some time afterwards, the gel particles cannot coalesce, but are redissolved, i.e. "peptized." By adding brine about two-thirds sat. in a thin stream to the water-glass whilst this is mechanically stirred it is possible to increase the vol. of the water-glass soln. up to about 25 per cent. without impairing the viscosity or adhesive properties of the liquid, which will contain from 3-4 per cent. of sodium chloride. The final viscosity of the soln. may be varied to a considerable extent by small changes in the conc. of the brine. The treated adhesive does not deteriorate when kept out of contact with the air.

Water-glass is used in preparing fireproof cements and lutings for jointing firebricks, etc. These can be made to set hard in the cold by admixture with lime, which causes the precipitation of gelatinous silica. The joint can be further strengthened by heat so as to form a fused silicate. Mixtures of conc. water-glass liquor and fibrous asbestos also make a good packing for joints exposed to hot acid vapours. J. N. von Fuchs used it for reducing the inflammability of wood. Walls plastered with lime-mortar are rendered hard and smooth, and capable of being washed, by applying a few coats of water-glass either alone or mixed with a colouring oxide. In the so-called *stereochrome process* of mural decoration, devised by J. N. von Fuchs in 1840, a plastered surface is decorated by pigments mixed with water, and the colours are then fixed by spraying with water-glass. The lime in the plaster fixes the silicate. The subject has been discussed by H. Creuzburg, F. C. Kuhlmann, etc. J. N. von Fuchs showed the possibility of making artificial stone by moulding a mixture of clay, sand, and a soln. of water-glass; F. Ransome patented an artificial stone made from sand water-glass, and powdered limestone or chalk; Brunner-Mond used it for hardening concrete roads; and L. Wagenmann made an artificial meerschäum by mixing water-glass, lime, magnesia, and magnesium carbonate. F. C. Kuhlmann said that lime-mortar can be made hydraulic by admixture with a small proportion of powdered water-glass. Water-glass is used as a hardening agent for the surface of concrete; in making soaps and washing fluids of various kinds; in paper-making; as egg-preserved; as a remedy for boiler-scaling; and in maintaining the fluidity of clay-slip with a large proportion of clay for the casting of fireclay goods, sanitary ware, earthenware, etc. It is also used as a detergent.⁴

The alkali silicates.—In his study of the mol. formula of silica, P. Yorke⁵ tried the action of silica on the alkali carbonates at a high temp. He found that a mol of carbon dioxide is expelled from a mol of lithium carbonate by half a mol of silica, forming presumably the orthosilicate, Li_4SiO_4 ; and observations were also made with sodium and potassium carbonates. H. Rose, T. Scheerer, E. Mallard, and P. Ebell studied the expulsion of carbon dioxide from fused potassium and sodium carbonates by silica. In general, the proportions depend on the temp., the duration of the experiment, and on the relative proportions of silica and alkali carbonate. P. Yorke, and C. L. Bloxam also studied the expulsion of water from molten potassium and sodium hydroxides by silica. J. M. Ordway likewise studied the expulsion of sulphur trioxide from molten sodium sulphate, by silica.

E. J. Mills and D. Wilson investigated the distribution of potassium oxide between silica and carbon dioxide, and said that, owing to the evolution of carbon dioxide, the reaction is incapable of simultaneous inversion. N. M. von Wittorf obtained the results with various alkali oxides indicated in Table XII. There is evidence of the loss of rubidium and caesium oxides by volatilization. P. Niggli has criticized these results, and made a more extended study of ternary systems containing one volatile and two non-volatile components; and of a portion of the system $\text{R}_2\text{O}-\text{SiO}_2-\text{CO}_2$ with a more accurate control of the press. and temp. than was the case in N. M. von Wittorf's experiments. P. Niggli found that in the case of potassium carbonate there is an equilibrium reaction: $\text{K}_2\text{CO}_3 + \text{K}_2\text{Si}_2\text{O}_5 \rightleftharpoons \text{CO}_2 + 2\text{K}_2\text{SiO}_3$, and at 898° , $K_1 = [\text{K}_2\text{SiO}_3][\text{CO}_2]/[\text{K}_2\text{CO}_3][\text{K}_2\text{Si}_2\text{O}_5]$ varies from 0.44-1.65; and at 956° , K_2 varies from 1.21-2.52; while K_1/K_2 is nearly

TABLE XII.—DISTRIBUTION OF THE ALKALI OXIDES, CARBON DIOXIDE, AND SILICA.

Initial mixture (molar).	Molar proportions after fusion.							
	CO ₂ 0.7 atm.				CO ₂ 1.0 atm.			
	Temp.	CO ₂	SiO ₂	R ₂ O	Temp.	CO ₂	SiO ₂	R ₂ O
Li ₂ CO ₃ +SiO ₂	—	0	1	1	—	0	1	1
4Li ₂ CO ₃ +SiO ₂	900°	1.74	1	4	900°	1.04	1	4
Na ₂ CO ₃ +SiO ₂	—	0	1	1	825°	0	1	1
2Na ₂ CO ₃ +SiO ₂	870°	0.69	1	2	780°	0.78	1	2
K ₂ CO ₃ +SiO ₂	870°	0.18	1	1	780°	0.24	1	1
Rb ₂ CO ₃ +SiO ₂	870°	0.22	1	1	825°	0.29	1	0.99
Cs ₂ CO ₃ +SiO ₂	870°	0.27	1	0.94	825°	0.38	1	0.95

constant, 2.2. With sodium carbonate, the equilibrium reaction is symbolized $\text{Na}_2\text{CO}_3 + \text{Na}_2\text{SiO}_3 \rightleftharpoons \text{CO}_2 + \text{Na}_4\text{SiO}_4$; and with lithium carbonate, probably $2\text{Li}_2\text{CO}_3 + \text{Li}_4\text{SiO}_4 \rightleftharpoons \text{Li}_8\text{SiO}_6 + 2\text{CO}_2$. The effect of press. in the case of the potassium carbonate system is complex. * He found that if the total press. acting on the melt is equal to the partial press. of carbon dioxide, the magnitude of the effect produced by change of press. will be somewhat different. Consider a very high press. of carbon dioxide. The progress of the reaction is accompanied by a considerable increase of vol. so long as the carbon dioxide is set free as a gas; consequently, if this condition obtains, increase of press. displaces the equilibrium towards the left, i.e. favours the substances K_2CO_3 and $\text{K}_2\text{Si}_2\text{O}_6$. If the carbon dioxide produced should be completely absorbed by the melt, the vol. change would be slight, and its direction could not be predicted; but there is a second effect produced in this case; for change of press. of carbon dioxide in the gas phase brings about, in accordance with Henry's law, a change of conc. of free carbon dioxide in the melt, and in this way displaces the equilibrium. Indeed, it is largely upon the increase, with increasing press. of the solubility of the gas in the melt that the resultant effect will depend.

In each system, the compound containing more silica is the poorest in silica which can be prepared pure, at the particular temp., merely by melting together carbonate and silica. Thus, K_2SiO_3 or Na_4SiO_4 or Li_8SiO_6 cannot be prepared in the pure state from carbonate and silica at about 1000°; the compounds $\text{K}_2\text{Si}_2\text{O}_6$, Na_2SiO_3 , and Li_4SiO_4 , which have relatively more silica, can readily be obtained.

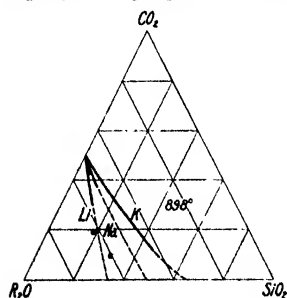

FIG. 56.—Relative Concentrations of R_2O , SiO_2 , and CO_2 in Equilibrium in Melts at 898°.

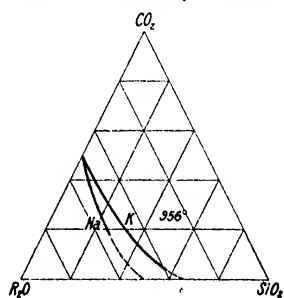

FIG. 57.—Relative Concentrations of R_2O , SiO_2 , and CO_2 in Equilibrium in Melts at 956°.

Correspondingly, in Figs. 56 and 57, the equilibrium curves or their prolongations pass through these particular points on the side $\text{R}_2\text{O}-\text{SiO}_2$. When alkali carbonate

is melted up with silica, the amount of carbon dioxide displaced in the temp. region of the ternary equilibrium ranges from 0.5–1.0 eq. in the potash system, from 1–2 eq. in the soda system, and from 2–4 eq. in the lithia system. The extent of the displacement of carbon dioxide from the carbonate by silica is parallel with the amount of carbon dioxide which the pure carbonate when melted alone loses by dissociation, when the systems are taken in order as above; the relative compositions of the pairs of silicates in equilibrium in each system is such that the ratio of base to silica for the right-hand member of one system is the same as for the left-hand member of the following system. Rise of temp., the press. remaining constant, favours in each case the silicate poorer in silica; or, in other words, it increases the amount of carbon dioxide displaced.

G. W. Morey and C. N. Fenner studied the ternary systems, K_2SiO_3 – SiO_2 – H_2O , and determined the composition and properties of the solid phases which can coexist with soln. and vap. between 200° and 1000° —vide Fig. 58; the composition of the soln. in equilibrium with the solid phases; the change in the composition of the soln. with temp.; and of the corresponding three-phase pressure, Fig. 59, shows the isothermal polybasic saturation curves, and the polythermal curve at one atm. press.

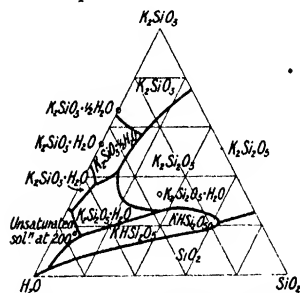

FIG. 58.—Stability Regions of the Solid Phases in the Ternary System, K_2SiO_3 – SiO_2 – H_2O .

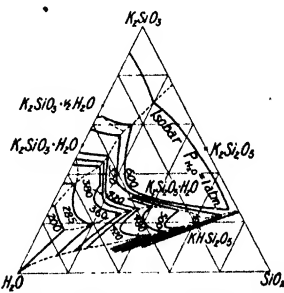

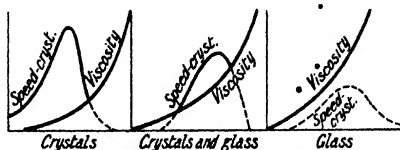

FIG. 59.—Isothermal Polybasic Saturation Curves; and an Isobasic Polythermal Curve in the Ternary System, K_2SiO_3 – SiO_2 – H_2O .

The fusibility of some mixtures of the alkali oxides and silica were observed by W. A. Lampadius, N. G. Sefström, and P. Berthier in their studies on slags. C. J. Peddle studied the glasses obtained from the binary and ternary systems with the components SiO_2 – Na_2O – K_2O . The thermal diagrams of the alkali oxides and silica have not been obtained in a complete form because in some regions glasses only are produced and the cooling or heating curves of these exhibit no breaks. There is therefore a continuous gradation in the composition of these glasses, and no evidence of the formation of definite chemical individuals. E. Kittl found it impossible to measure the ratios of crystallization of the alkali silicate glasses. He inferred that there is a close relation between the viscosity of a molten silicate and its speed of crystallization. When the maximum speed of crystallization falls in the region of low viscosity, complete crystallization usually occurs, Fig. 61, while in the opposite case, a glass is formed, Fig. 62. In the intermediate case, both glass and crystals are formed, Fig. 61. P. Bary discussed the alkali silicate glasses.

FIGS. 60–62.—Relation between the Viscosity and the Speed of Crystallization.

Many of the alkali silicates described by the early workers are simply alkali silicate-glasses whose compositions corresponded with those which would be the case if the alleged silicates were chemical individuals; and this in spite of the fact that constitutional formulæ were sometimes assigned to them. W. Pukall, for instance, described a number of what he regarded as specific silicates but which he described as clear transparent glasses. Similar remarks apply to the alkali silicates obtained by saturating soln. of alkali hydroxide with silica; and to the precipitates obtained by adding alcohol to an alkali soln. of silica. Thus, G. Forchhammer⁶ reported that he prepared $K_2O \cdot 2SiO_2$, $K_2O \cdot 8SiO_2$, and $Na_2O \cdot 3SiO_2$ by alcohol precipitation, but J. M. Ordway showed that actually the composition of the precipitate depends (i) on the conc. of the soln.; (ii) on the proportion of alkali present; and (iii) on the amount of alcohol added. The composition of the precipitate can be made to vary continuously by variations in these conditions so that the composition of G. Forchhammer's silicates represent arbitrarily selected points on a continuous curve.

The above remarks apply to T. Scheerer's $Na_2O \cdot SiO_2$ and $4K_2O \cdot 3SiO_2$; to A. Lielegg's $Na_2O \cdot 2SiO_2$; to P. Ebell's $2Na_2O \cdot 5SiO_2$; to G. Forchhammer's $Na_2O \cdot 3SiO_2$, $K_2O \cdot 2SiO_2$, $K_2O \cdot 4SiO_2$, and $K_2O \cdot 8SiO_2$; to A. I. Walker's $Na_2O \cdot 4SiO_2 \cdot 10H_2O$; and to G. Forchhammer's $Na_2O \cdot 36SiO_2 \cdot 4H_2O$ and $K_2O \cdot 24SiO_2 \cdot 16H_2O$. The two last-named products are probably silica hydrates with absorbed potassium hydroxide. The product $K_2O \cdot 4SiO_2$ was also discussed by J. N. von Fuchs, B. von Ammon, J. von Liebig, H. V. Regnault, J. M. Ordway, and P. Ebell; $K_2O \cdot 8SiO_2$, by P. Ebell; $Na_2O \cdot 2SiO_2$, by A. Scheurer-Kestner, J. M. Ordway, T. Graham, A. Bornträger, and F. Kohlrausch; $2Na_2O \cdot 5SiO_2$, by W. Selezneff, F. Kohlrausch, and F. Mylius. Trisilicate glasses, $2R_2O \cdot 3SiO_2$, were also described by E. Frémy, and E. Grosechuff; $Na_2O \cdot 3SiO_2$, by T. Scheerer; $Na_2O \cdot 4SiO_2$, by J. M. Ordway, W. Heintz, A. Bornträger, R. Meyer, and J. W. Cobb. W. Pukall's *potassium trisilicate*, $K_2Si_3O_8$, and *sodium trisilicate* were glasses; likewise also his *potassium or sodium tetrasilicate*, $K_2Si_4O_{10}$ and $Na_2Si_4O_{10}$; *potassium or sodium pentasilicate*, $K_2Si_5O_{15}$ or $Na_2Si_5O_{15}$; and his *potassium or sodium hexasilicate*, $R_2Si_6O_{18}$. He obtained the hexasilicates in a devitrified state.

A solid **ammonium silicate** has not been isolated. The solubility of silica or silicic acid in aq. ammonia has been previously discussed. C. Struckmann⁷ found that 100 parts of a 5 per cent. soln. of ammonium carbonate dissolved 0.02 part of silicic acid, and 100 parts of a 1 per cent. soln. dissolved 0.002 part of silicic acid. The soln. on standing in air became turbid owing to the separation of about half the dissolved silica. R. Schwarz showed that the solubility of silicic acid in aq. ammonium depends on the conc. of the ammonia, the temp., and the water content and physical form of the acid. R. Schwarz and O. Liede used quartz-glass vessels in order to eliminate the influence of alkalis derived from the glass containing vessels; the soln. were also filtered through an ultra-filter to retain colloidal silica. It was found that with silicic acid, equilibrium is attained after about 72 hrs. at 18°, and that the soln. contains 64 per cent. of the silica in true soln., 8 per cent. in colloidal soln., and 28 per cent. undissolved. The conductivity and solubility curves show that the amount of dissolved silica increases during the whole course of the experiment, whilst the colloidal silica gradually diminishes in quantity. The former therefore grows at the expense of the latter, and it appears justifiable to conclude that the formation of the colloidal soln. is the primary process which is followed by the production of the molecular soln.

According to C. Struckmann, the silicic acid, precipitated by ammonium carbonate from a soln. of an alkali silicate, and washed with water until the runnings give no turbidity with mercuric chloride, and washed with water until the runnings develop ammonia when treated with potassium hydroxide, and when dried in air, retains 0.78 per cent. of ammonia. The product obtained when ammonium chloride is the precipitant contains less ammonia. J. von Liebig, however, claimed that all the ammonia could be removed by washing. R. Schwarz showed that it is not always clear whether ammonia really neutralizes the silicic acid, or merely produces a colloidal soln. E. Jordis and E. H. Kanter showed that the electrical conductivity of a soln. of silicic acid

prepared by dialysis, and mixed with aq. ammonia, indicates that **ammonium hydrosilicate**, $\text{H}(\text{NH}_4)\text{SiO}_3$, and **ammonium metasilicate**, $(\text{NH}_4)_2\text{SiO}_3$, are probably present; there is, however, no definite proof that **ammonium orthosilicate**, $(\text{NH}_4)_4\text{SiO}_4$, is present. According to R. Schwarz, the solubility of the hydrate, $3\text{SiO}_2 \cdot \text{H}_2\text{O}$, in 3*N*-ammonia at 18° reaches a maximum in about two hundred hours, corresponding with about one-fiftieth of the amount of acid required to form a metasilicate; in 10*N*-ammonia at 100° the solubility after one hour reaches 84.3 per cent.; in 2*N*-ammonia at 100° the hydrate dissolves to the extent of 55.7 per cent., ignited precipitated silica to the extent of 24.4 per cent., both in one hour, whilst finely powdered quartz only loses 2.7 per cent. of its weight in a day. Soln. obtained in the hot way have the appearance of colloidal soln., but the cold preparations are clear. Inasmuch as the conductivity of the ammonia soln. rises with time (in the case of the hydrate, with negative acceleration: in the case of the anhydride, with positive acceleration during the first one hundred hours), the formation of a true ammonium silicate seems to be certain. Although the salt cannot well be isolated, the nearly related **tetraethylammonium metasilicate**, $(\text{NEt}_4)_2\text{SiO}_3$, can be obtained as a hygroscopic, amorphous powder by heating the silicic acid hydrate with 10 per cent. tetraethylammonium hydroxide in a sealed tube at 80°. R. Schwarz found that dioxodisiloxane, made by leading trichloromonosilane vap. into water, reacts with ammonia soln. just as it does with potassium or sodium hydroxide, that is, according to the equation $\text{Si}_2\text{H}_2\text{O}_3 + 4\text{NH}_4\text{OH} = 2(\text{NH}_4)_2\text{SiO}_3 + 2\text{H}_2 + \text{H}_2\text{O}$. The reaction is completed in about twenty minutes, and most of the silica, with which specimens of dioxodisiloxane are usually contaminated, remains as a precipitate. R. Schwarz and R. Soudard studied the electrical conductivity of soln. of silicic acid and inferred from the increment of the conductivity that salt formation does take place just as the lowering of the conductivity of sodium hydroxide by the addition of silicic acid leads to a similar conclusion. The ratio *Q* of the increment in conductivity to the dissolved silica decreases in three stages as the proportion of water in the silicic acid is diminished. The value of *Q* is about 75 when the silicic acid has 4.5 per cent. of water, about 50 when about 2.0 per cent. of water is present, and about 25 when the silicic acid is almost dry. All the different preparations of silicic acid gave *Q*=25 when the specimen was nearly dry, and *Q*=75 when the specimen was rich in water. After ignition, however, silica causes no increment in the conductivity of ammonia soln. The different values of *Q* suggest, therefore, that the dissolved silicic acid exists in three forms with mol. wts. in the ratio 1 : 2 : 3. The simplest forms of silicic acid are derived from dioxodisiloxane or monosilicic, the direct hydrolysis of the latter in ammonia soln. being the most satisfactory way of preparing ammonium silicate soln.

K. A. Vesterberg⁸ found that amorphous silica dried at 100° dissolves slowly in 2*N*-LiOH at ordinary temp., forming a soln. with 3.4 mols of silica to one mol of Li_2O . In warm soln. of lithium hydroxide, silica is almost insoluble, being transformed into an insoluble lithium silicate. P. Yorke prepared **lithium orthosilicate**, Li_4SiO_4 , by heating lithium carbonate and silica in equimolar proportions; and N. M. von Wittorf found that **lithium metasilicate**, Li_2SiO_3 , is also formed. K. A. Vesterberg prepared monohydrated lithium metasilicate in two forms, one insoluble, the other soluble. The former is produced as a white, granular precipitate by adding a fairly conc. soln. of sodium metasilicate to an eq. quantity of lithium hydroxide or chloride in *N*-soln. at 80°-90°; it is also obtained by dissolving freshly precipitated silicic acid in twice the theoretical amount of 2*N*-LiOH at ordinary temp., and heating the soln. a short time at 80°. According to P. Hautefeuille and J. Margottet, fused lithium chloride has no action on amorphous silica so long as no trace of lithium oxychloride is present; but if by the action of steam, or other agents, a little oxychloride is present, then the silica is converted into quartz or tridymite according to the temp. If much oxychloride is present, plates of **lithium pentasilicate**, $\text{Li}_2\text{Si}_5\text{O}_{11}$, or $\text{Li}_2\text{O} \cdot 5\text{SiO}_2$, are formed. They prepared the three

silicates just mentioned by melting together silica and lithia with or without lithium chloride; in the one case measurable crystals are formed, and in the other case a crystalline mass is obtained. The three silicates were said to be as difficult to fuse as the magnesium silicates, and when melted, they form very fluid liquids and absorb much gas, which is rejected on cooling. Lithium chloride abstracts lithia from the lithium silicates, forming the oxychloride. According to H. S. van

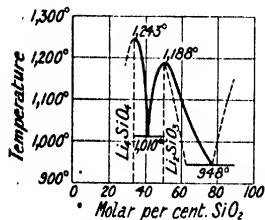

FIG. 63.—Freezing-point Curve of the Binary System: $\text{Li}_2\text{O}-\text{SiO}_2$.

Klooster, the binary system $\text{Li}_2\text{O}-\text{SiO}_2$ forms only two compounds, which are only slightly miscible in the crystalline state. There is no evidence of the formation of the pentasilicate $\text{Li}_2\text{Si}_5\text{O}_{11}$ on the thermal diagram, Fig. 63. No crystalline products were obtained with over 82 per cent. silica. R. Rieke and K. Endell also explored the thermal diagram, and the results confirm those of H. S. van Klooster. The eutectic between the ortho- and meta-silicate, at about 1010° and 47.5 per cent. silica, corresponds in composition with $3\text{Li}_2\text{O} \cdot 2\text{SiO}_2$. They said that microscopically this mixture does not show any evidence of the eutectic structure, and suggest that there may be really a very small maximum corresponding with lithium orthosilicate, $\text{Li}_6\text{Si}_2\text{O}_7$. F. M. Jäger and H. S. van Klooster obtained the orthosilicate in large tabular biaxial crystals of sp. gr. 2.454 at 25°; and indices of refraction with the *D*-ray, 1.545 and 1.525. At 1032°, there is an incongruent m.p., and a solid soln. of the orthosilicate in an excess of the metasilicate is formed. A. Rosenheim and W. Reglin studied the adsorption of lithium hydroxide from soln. by lithium silicate. P. Yorke, P. Hautefeuille and J. Margottet, R. Schwarz, and A. Haacke obtained lithium orthosilicate, as indicated above, by fusing together silica and a lithium salt. The conditions of formation, by W. Pukall, H. S. van Klooster, and R. Rieke and K. Endell, are indicated in Fig. 63. The last-named found that the fused glass is readily undercooled. E. Derome said that when the glass obtained by heating at 900° a mixture of lithium carbonate and silica in a current of hydrogen for a few hours, is heated in vacuo by an electric furnace, slow dissociation occurs, and lithia is volatilized until the composition of the residue approximates to that of the orthosilicate, when volatilization ceases. P. Niggli found that the orthosilicate is readily obtained from lithium carbonate and silica at about 1000°. P. Hautefeuille and J. Margottet said that the transparent, colourless, or slightly amber-coloured crystals are similar to peridot, and when crystallized from lithium chloride they form pseudo-hexagonal prisms derived from rhombic prisms. R. Rieke and K. Endell said that the crystals are greenish coloured if made in a platinum vessel. H. S. van Klooster found the sp. gr. to be 2.346 at 15°/15°, and F. M. Jäger and H. S. van Klooster, 2.392 at 25°/15°. The hardness is 3-4 on Mohs' scale. A. Haacke gave 2.280 for the sp. gr., and 1249° for the m.p. H. S. van Klooster found that the f.p. is 1188°, and the m.p. 1243°, and F. M. Jäger and H. S. van Klooster, 1256°; according to R. Rieke and K. Endell, 1215°. R. Ballo and E. Dittler gave 1217° for the m.p.; and R. Schwarz, 1249°. H. S. van Klooster found that in polarized light the crystals are feebly doubly refracting; and they exhibit twinning. R. Ballo and E. Dittler obtained cellularly arranged crystals with refractive index, 1.616-1.624. F. M. Jäger and H. S. van Klooster gave 1.614 and 1.694 for the indices of refraction. The crystals appeared to be optically biaxial, with very small axial angle, or optically uniaxial, and always positive. F. M. Jäger and H. S. van Klooster suggest that 1256° is rather a transition temp. than a m.p. P. Niggli added the salt furnishes irregular equidimensional grains, without crystal outline and characterized by an albite-like twinning with large extinction angle; a second set of twinning striations inclined to the first is less well developed. The crystals are optically biaxial with very small axial angle; positive; mean index of refraction is in the neighbourhood of

1.600; birefringence is fairly strong. P. Hautefeuille and J. Margottet, and H. S. van Klooster found that the crystals become flinty in appearance when in contact with water owing to a superficial decomposition; when boiled with water, some silica and lithia are dissolved; the decomposition by water, said R. Rieke and K. Endell, is complete. W. Pukall said that some *hydrate* of the orthosilicate, $\text{Li}_4\text{SiO}_4 \cdot 2.57\text{H}_2\text{O}$, remains as a residue when the anhydrous orthosilicate is decomposed by water. The salt is attacked by acids; and the resistance of the silicates to chemical agents increases as the silica increases.

P. Hautefeuille and J. Margottet prepared lithium metasilicate as indicated above; and G. Friedel, by heating a soln. of lithium hydroxide with an excess of precipitated silica to 500° in a steel tube. H. S. van Klooster, and R. Rieke and K. Endell showed that the conditions of formation are those represented in Fig. 63. According to P. Hautefeuille and J. Margottet, the silicate crystallizes from molten lithium chloride in long flat prisms sometimes terminating in symmetrical domes; they are six-sided, and are derived from rhombic prisms. According to G. Friedel, the colourless crystals resemble those of hypersthene, and the rhombic prisms have the axial ratio $a:c=1:0.6681$, and $\alpha=107^\circ 48'$. F. M. Jäger and H. S. van Klooster state that the biaxial crystals are probably monoclinic, and that the trigonal form of G. Friedel was a twin formation. E. Kittl studied the velocity of crystallization of lithium ortho- and meta-silicates. The sp. gr. is 2.529 at $15^\circ/15^\circ$; and R. C. Wallace gave 2.61 at 18° . F. M. Jäger and H. S. van Klooster gave 2.520 for the sp. gr. of the crystals, and 2.330 for the sp. gr. of the glass at 25° . H. S. van Klooster said that the metasilicate forms mixed crystals with up to 24.3 per cent. of silica; and that the m.p. is 1188° ; while R. Rieke and K. Endell gave 1180° ; R. C. Wallace, 1168° ; F. M. Jäger and H. S. van Klooster, 1201° ; and R. Ballo and E. Dittler, 1180° . F. M. Jäger found the surface tension at 1254° to be 374.6 dynes per sq. cm., and at 1601° , 346.6 dynes per sq. cm. According to E. Derome, when the metasilicate is heated in vacuo in an electric furnace, dissociation and volatilization of lithia occurs until there is an abrupt slackening of the speed when the composition approaches $\text{Li}_2\text{Si}_2\text{O}_{11}$. R. C. Wallace said that the mica-like crystals have a high refractive index, and a very high double refraction, with polarization colours of the third and fourth orders. The optical properties were also discussed by H. S. van Klooster, and R. Rieke and K. Endell. F. M. Jäger and H. S. van Klooster gave 1.609 and 1.584, with the D-ray, for the indices of refraction of the crystals parallel and vertical to the elongation of the needles; they also gave $\mu=1.548$ for the glass. As P. Hautefeuille and J. Margottet, G. Friedel, and R. Rieke and K. Endell have shown, the crystals are decomposed by water and by acids; the latter say that the crystals are less decomposed by water than the other alkali metasilicates. L. Kahlenberg and A. T. Lincoln made aq. soln. up to a conc. of $\frac{1}{32}$ mol. per litre by gradually adding the alkali hydroxide to a colloidal soln. of silicic acid; they determined the lowering of the f.p. of soln. containing a mol of Li_2SiO_3 in v litres of water and found:

v	32	48	64	96	128
Lowering f.p.	0.228	0.166	0.120	0.090	0.070
Calc. mol. wt.	23.3	23.2	22.1	19.6	18.5

It was therefore inferred that when $v=32$, 95.5 per cent. of the salt is decomposed, and when $v=48$, the decomposition is practically complete. For the eq. conductivity, λ , at 25° , they found:

v	32	64	128	256	512	1024
λ	125.0	126.0	129.2	130.2	138.5	145.2

The increase beyond $v=64$ is said to be due to the decrease in the retarding influence of silicic acid on the movements of the ions. K. A. Vesterberg found that warm soln. of lithium hydroxide only slowly dissolve precipitated silica dried at 100° ; and cold, moderately conc. soln. dissolve up to 3.4 mols. of SiO_2 per mol of Li_2O . He prepared **hydrated lithium metasilicate**, $\text{Li}_2\text{SiO}_3 \cdot \text{H}_2\text{O}$, by treating

sodium silicate with a lithium salt, or by dissolving silica in a solid soln. of lithium hydroxide. In both cases an excess of lithia should be present to prevent hydrolysis. The silicate is precipitated from the soln. at 80°–90°. There are two forms of this salt, one is readily soluble but the other dissolves with difficulty.

While H. S. van Klooster, and R. Rieke and K. Endell could find no evidence of the formation of lithium pentasilicate, $\text{Li}_2\text{Si}_5\text{O}_{11}$, P. Hautefeuille and J. Margottet obtained flexible rhombic lamellæ by crystallization from a soln. of the component in lithium chloride. There is a cleavage plane in the direction of greatest length, one perpendicular to that direction, one parallel to the plane of the lamellæ, and two others which furnish thin rhombic plates. E. Derome found that the speed of volatilization of lithia from lithium metasilicate suddenly slackens when the composition has reached $\text{Li}_2\text{O} \cdot 5\text{SiO}_2$, and that the latter is slightly dissociated in vacuo at 1300°. P. Hautefeuille said that this silicate is not decomposed by acids. L. Kahlenberg and A. T. Lincoln found that the lowering of the f.p. of soln. of lithium hydroxide in a colloidal soln. of silica corresponding with a mol of $\text{Li}_2\text{Si}_5\text{O}_{11}$ in v litres, is:

v	32	48	64	96	128
Lowering f.p.	0.172	0.130	0.112	0.077	0.062
Mol. wt.	113.2	93.3	86.9	84.3	78.5

This is taken to show that the salt $\text{Li}_2\text{Si}_5\text{O}_{11}$ is hydrolytically dissociated in aq. soln., and the dissociation is complete when $v=128$; eq. electrical conductivity, λ , is:

v	32	64	128	256	512	1024
λ	55.4	61.6	67.5	72.6	78.9	90.6

As indicated previously, P. Niggli obtained evidence of the formation of a basic orthosilicate or **lithium dioxorthosilicate**, $\text{Li}_6\text{Si}_6\text{O}_{16}$, or $2\text{Li}_2\text{O} \cdot \text{Li}_4\text{SiO}_4$.

According to E. Jordis,⁹ crystal plates of what is probably **sodium orthosilicate**, Na_4SiO_4 , is formed when a mol of silica is fused in a silver crucible with 8 mols of sodium hydroxide; while an aq. soln. of sodium hydroxide and silica with more than $14\text{Na}_2\text{O} : \text{SiO}_2$ furnishes crystals of the hydrated sodium metasilicate, $\text{Na}_2\text{SiO}_3 \cdot n\text{H}_2\text{O}$. W. G. Mixer calculated the heat of combination of silicon with an excess of sodium dioxide forming sodium orthosilicate. P. Niggli found evidence of the existence of sodium orthosilicate in his study of the ternary system $\text{Na}_2\text{O} \cdot \text{SiO}_2 \cdot \text{CO}_2$, but did not isolate the compound—*vide supra*. The stable silicates in this system are the ortho- and meta-silicates. G. W. Morey failed to make **potassium orthosilicate**, K_4SiO_4 , by melting potassium hydroxide in various proportions between K_4SiO_4 and K_2SiO_3 in an atm. of steam, and heating the mass finally over 1100°. The excess of alkali over that required for the metasilicate was present as potassium hydroxide. P. Niggli obtained no evidence of the formation of potassium orthosilicate in his study of the ternary system $\text{K}_2\text{O} \cdot \text{SiO}_2 \cdot \text{H}_2\text{O}$; the metasilicate was always produced. The stable silicates here produced were the meta- and disilicates.

P. Niggli obtained crystals of anhydrous sodium metasilicate, Na_2SiO_3 , from dry melts by heating an intimate mixture of eq. quantities (1 : 1) of quartz and sodium carbonate at 900°–1000° for some time. With less quartz, the system is heterogeneous. G. W. Morey also obtained evidence of the formation of this silicate when a glass of the composition $\text{Na}_2\text{O} : \text{SiO}_2$ is heated with water at temp. above 400°. The isolation of the crystals is not possible because they are rapidly decomposed by water. W. Pukall obtained a devitrified glass. G. W. Morey and C. N. Fenner found that the crystals are rarely well developed and fibrous and spherulitic forms are frequent; hexagonal prisms terminated by prisms were once obtained. The crystals prepared by G. W. Morey were usually acicular. In both cases, cleavage is well developed and parallel to the elongation. The crystals show parallel extinction. The compound is probably uniaxial and positive. The index of refraction $\gamma=1.520$, and the α -index is lower; the mean value is 1.510. R. C. Wallace also obtained ill-defined crystals by heating the hydrated meta-

silicate, and also by heating an eq. mixture of silica and sodium carbonate. The latter mixture crystallizes after the first fusion, the former needs to be repeatedly cooled and remelted before crystallization begins. It is assumed that in the latter case a small amount of water is retained even after fusion, and that this retards crystallization. R. C. Wallace gave 1018° for the m.p. of sodium metasilicate; W. Guertler, 1055°; and N. V. Kultacheff, 1007°. The latter found that the metasilicate can dissolve a little silica, and that this lowers the m.p. a little. According to G. Tammann, the heat of crystallization is 29 cal. per gram. G. W. Morey found the m.p. of sodium metasilicate appears 2° lower on the heating curve than on the cooling curve. The sp. hts. of crystals and glass were respectively 0.197 and 0.191. P. Niggli, and R. C. Wallace found that when the metasilicate is heated with quartz no combination occurs, although the latter found that the metasilicate can take up a little silica in solid soln. E. Greiner studied the viscosity of the molten silicate. The last-named also found the m.p. to be lowered by the addition of silica; thus:

Silica (per cent.)	0	2.5	3.7	5.0	6.5
M.p.	1007°	942°	920°	862°	820°

G. Tammann found the sp. ht. of the amorphous salt to be 0.191 and of the crystalline salt 0.197 between 20° and 100°; while the heat of soln. of a gram of the amorphous salt in a mixture of 100 grms. of 10 per cent. hydrofluoric acid and 250 grms. of *N*-hydrochloric acid was found to be 486 cal., and 457 cal. for the crystalline salt. C. Matignon gave $\text{Na}_2\text{SiO}_3(\text{solid}) + 2\text{HCl}(\text{soln.}) = \text{SiO}_2(\text{Aq. solid}) + 2\text{NaCl} + \text{H}_2\text{O} + 32.8$ cal.; consequently, from known reactions, $\text{SiO}_2(\text{Aq. solid}) + \text{Na}_2\text{O} = \text{Na}_2\text{SiO}_3 + 51.1$ cal.; $\text{SiO}_2(\text{Aq. solid}) + \text{Na}_2\text{CO}_3 = \text{Na}_2\text{SiO}_3 + \text{CO}_2 - 24.7$ cal.; and $\text{Si}_{\text{cryst.}} + 3\text{O} + 2\text{Na} = \text{Na}_2\text{SiO}_3 + 331.4$ cal. When the result 51.10 cal. is compared with D. Tschernobaeff's value 45.2 cal. for anhydrous silica, and O. Mulert's 69.7 cal., it appears as if some erroneous deductions have been made somewhere. W. W. Coblenz found a maximum in the reflection of ultra-red rays at 9.95 μ . J. O. Perrine observed no sign of the excitation of fluorescence by the X-rays.

G. W. Morey found anhydrous **potassium metasilicate**, K_2SiO_3 , to be the stable solid phase in the binary system $\text{K}_2\text{SiO}_3\text{--H}_2\text{O}$ from about 610° to its m.p., and it is obtained in a fairly pure condition by crystallizing the metasilicate glass at a high temp. The crystals usually appear in the form of rounded grains without crystal boundaries. There is evidence of cleavage parallel to the γ -axis. W. Pukall obtained only a metasilicate glass. G. W. Morey and C. N. Fenner found that the crystals are biaxial; the optical character is positive; the dispersion is strong and the birefringence high. The optic axial angle is 78.5°. The m.p. is 966°. The crystals are very hygroscopic and dissolve rapidly in water. The deliquescence of the hydrates makes their separation difficult; and they have not been isolated even in an approximately pure condition. M. A. Rakuzin measured the electrical conductivity of soln. of potassium metasilicate; and the reversible adsorption of the salt with animal charcoal, colloidal silica, and alumina.

In his study of the binary system $\text{K}_2\text{SiO}_3\text{--H}_2\text{O}$, G. W. Morey found that **hemihydrated potassium metasilicate**, $\text{K}_2\text{SiO}_3 \cdot \frac{1}{2}\text{H}_2\text{O}$, is the stable solid phase between 370°–610°—vide Figs. 58 and 64. The crystals occurred in elongated forms with good cleavage parallel to the elongation. The extinction was parallel to

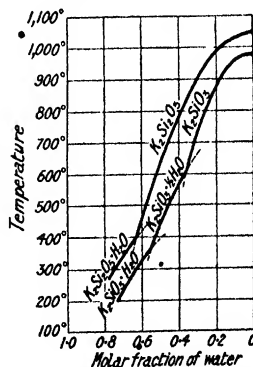

FIG. 64.—The Solubility or Melting-point Curves of the Binary Systems: $\text{K}_2\text{SiO}_3\text{--H}_2\text{O}$ and $\text{K}_2\text{SiO}_3 \cdot \frac{1}{2}\text{H}_2\text{O}$.

the elongation in the γ -direction; the birefringence is high; the optic axial angle large; and the optical character is probably positive. The crystals are completely soluble in water. He also found **monohydrated potassium metasilicate**, $K_2SiO_3 \cdot H_2O$, to be the stable phase between 200° and 370° —*vide* Figs. 58 and 64. Below 200° , the monohydrate is hydrolyzed by water, and above 370° it forms the hemihydrate. The crystals are biaxial, positive, with a small axial angle, and high birefringence. The crystals dissolve completely in water. W. Pukall obtained what he suggested to be *dihydrated potassium metasilicate*, $K_2SiO_3 \cdot 2H_2O$, by the action of superheated steam on the metasilicate glass.

Crystals of hydrated sodium metasilicate have been reported by a number of investigators, but there is no agreement as to the degree of hydration. A. H. Erdenbrecher obtained hexagonal crystals of **tetrahydrated sodium metasilicate**, $Na_2SiO_3 \cdot 4H_2O$, m.p. about 85° . T. Petersen obtained colourless, monoclinic crystals of what he regarded as the *pentahydrate*, $Na_2SiO_3 \cdot 5H_2O$, with axial ratios $a:b:c=0.6961:1:1.2001$, and $\beta=95^\circ 50'$. The crystals become turbid when exposed to air, they melt in their water of crystallization, leaving a voluminous residue which is soluble in water. E. Jordis prepared crystals with 43.42 per cent. of water, when the theoretical value for the pentahydrate is 42.37 per cent. A. H. Erdenbrecher obtained no signs of the pentahydrate on the vap. press. curves. J. Fritzsche obtained rhombohedral trichlinic prisms which he regarded as the *hexahydrate*, $Na_2SiO_3 \cdot 6H_2O$, by dissolving equimolar proportions of silica and sodium hydroxide in water; when the soln. is conc. by evaporation, and allowed to stand for some days, it yields a crystalline mass which in more dil. soln. deposits hemispherical or fibrous masses, or yields a crystalline crust. E. Jordis obtained crystals with 45.81 per cent. of water when the theoretical value for the hexahydrate is 46.87 per cent. A. H. Erdenbrecher obtained monoclinic crystals of the hexahydrate and gave 62.5° for the m.p. P. Yorke fused 54 parts of sodium carbonate and 23 parts of silica; dissolved the cold cake in water; evaporated the aq. soln. in vacuo over sulphuric acid at ordinary temp., and in a few days obtained a crop of crystals which corresponded with the *heptahydrate*, $Na_2SiO_3 \cdot 7H_2O$. A. H. Erdenbrecher found no signs of this hydrate on the vap. press. curve. R. Hermann obtained white rhombic crystals from the mother-liquor obtained in the purification of soda. Their composition corresponded with the *octohydrate*, $Na_2SiO_3 \cdot 8H_2O$. L. Krafft reported crystals of the same composition to be present in a sand breccia from Sablenville. According to B. von Ammon, the crystals are monoclinic prisms with axial ratios $a:b:c=0.6352:1:0.6721$, and $\beta=109^\circ 48'$. R. Hermann said the crystals are very soluble in water, and have a caustic taste. They melt in their water of crystallization leaving behind a swollen white mass. B. von Ammon, and J. M. Ordway gave 45° for the m.p. R. Hermann's crystals were said to be permanent in air, but B. von Ammon found that the crystals effloresce in moist air, and take up carbon dioxide, but they do not absorb carbon dioxide from a dry atm. At 100° , or confined over conc. sulphuric acid, the crystals lose 27.21 per cent. of water; at 130° , 49.2 per cent.; and at 150° , 53.75 per cent. A. H. Erdenbrecher obtained no signs of the octohydrate on the vap. press. curves. J. Fritzsche found that besides the hexahydrate, he sometimes obtained crystals of the *ennehydrate*, $Na_2SiO_3 \cdot 9H_2O$, which A. E. Nordenskjöld found to be rhombic bipyramids with axial ratios $a:b:c=0.6888:1:0.3378$. The crystals effloresce over sulphuric acid and attract carbon dioxide from the atm. They melt at 40° to a syrupy liquid which solidifies when allowed to stand for some days. A. H. Erdenbrecher gave 47° for the m.p., and he measured the vap. press. A. Vesterberg also obtained the ennehydrate, and from the experiments on dehydration he inferred that a *trihydrate*, $Na_2SiO_3 \cdot 3H_2O$, as well as a hexahydrate exists. E. Jordis obtained crystals of the *dodecahydrate*, $Na_2SiO_3 \cdot 12H_2O$ —or possibly of the *henahydrate*, $Na_2SiO_3 \cdot 11H_2O$ —in small prisms; and R. Weber obtained the dodecahydrate by treating a soln. of water-glass with ether. It thus appears as if sodium metasilicate forms several hydrates, but the composition and range of stability of these hydrates are not known.

More knowledge will probably reduce the number ~~very~~ considerably. Thus A. H. Erdenbrecher's measurements of the vap. press. gave evidence of only the ennea-, hexa-, and tetra-hydrates, and the existence of a *tetradecahydrate*, $\text{Na}_2\text{SiO}_3 \cdot 14\text{H}_2\text{O}$, was made probable but not certain.

Dil. aq. soln. of sodium metasilicate are strongly hydrolyzed; E. H. Loomis found that the hydrolysis is complete in a $\frac{1}{10}$ N-soln., and 64.8 per cent. is hydrolyzed in a $\frac{1}{5}$ N-soln. L. Kahlenberg and A. T. Lincoln found the lowering of the f.p. of soln. of silica in sodium hydroxide lye in the proportions Na_2SiO_3 , NaHSiO_3 , and $\text{Na}_2\text{Si}_2\text{O}_5$ to be, for a mol. of the salt in v litres, at 25° :

v	8	16	24	32	64	96	128
Na_2SiO_3	0.695	0.385	0.280	0.210	0.110	—	—
Na_2SiO_3 (by fusion)	—	—	—	0.200	0.108	0.077	—
NaHSiO_3	0.332	0.202	0.146	0.110	—	—	—
$\text{Na}_2\text{Si}_2\text{O}_5$	—	—	—	0.178	0.139	0.089	0.059
K_2SiO_3	0.710	0.394	0.279	0.215	0.110	0.082	—
KHSiO_3	0.316	0.196	0.153	0.110	—	—	—
Rb_2SiO_3	—	—	—	—	0.139	0.098	—
Cs_2SiO_3	—	—	—	—	0.102	0.068	—

The values for the two sodium metasilicates are virtually the same. The corresponding mol. wts. approach as their limit one-fourth the mol. wt. of Na_2SiO_3 with increasing dilution; with sodium hydrometasilicate, the limiting mol. wt. is one-half that of NaHSiO_3 ; and with the pentasilicate, the limiting mol. wt. is one-fourth that of $\text{Na}_2\text{Si}_2\text{O}_5$. With the potassium metasilicates under similar conditions the hydrolysis is practically complete when $v=48$, and with $v=8$, the normal salt is ionized 66.9 per cent., and the acid salt, 39 per cent. R. H. Bogue also found the hydrolysis of the $\text{Na}_2\text{O} : \text{SiO}_2$ products from 1 : 1 to 1 : 4 was greatest with the first, and decreased as the proportion of silica increased. The results with **rubidium metasilicate**, Rb_2SiO_3 , and **caesium metasilicate**, Cs_2SiO_3 , are quite similar. The electrical conductivities, λ , of the soln. were determined by S. Arrhenius, F. Kohlrausch, E. H. Loomis, and L. Kahlenberg and A. T. Lincoln. The two last-named found at 25° :

v	8	16	32	64	128	256	512	1024
Na_2SiO_3	105.3	112.0	117.8	115.0	110.5	95.7	91.8	104.8
NaHSiO_3	72.4	78.8	84.9	90.1	103.7	114.2	133.1	148.5
$\text{Na}_2\text{Si}_2\text{O}_5$	—	—	73.0	79.9	87.3	93.1	101.1	113.3
K_2SiO_3	—	130.9	176.4	182.6	185.5	187.1	191.8	182.5
KHSiO_3	87.3	110.3	117.6	126.2	133.4	141.7	155.0	175.6

Similar results were obtained with rubidium and caesium metasilicates. It is assumed that hydrolysis is complete when $v=64$, and that the increase in the conductivity with soln. of greater dilutions is produced by the retarding influence of silicic acid on the movements of the ions. F. Kohlrausch noted that equilibrium in the hydrolysis is attained very slowly; that the temp. coeff. of the conductivity is abnormal, and that the age of the soln. has a marked influence on the results. He also inferred that $\text{Na}_2\text{Si}_2\text{O}_5$ is the sodium silicate richest in silica which can exist in aq. soln., and that aq. soln. of the metasilicate contain NaOH and $\text{Na}_2\text{Si}_2\text{O}_5$. E. Jordis, F. Mylius, F. Kohlrausch, L. Kahlenberg and A. T. Lincoln, and R. H. Bogue showed that in the hydrolysis of the alkali silicates, the silica separates in the colloidal form, and, in consequence, conclusions about the relative strength of silicic acid, based on the apparent degree of hydrolysis of such soln., are not necessarily valid; indeed, there is ground for the belief that silicic acid is considerably stronger than has generally been supposed, just as W. Blum showed to be the case with aluminic acid. In any case, solubility experiments, such as those made by A. Vesterberg, are meaningless, because the phenomenon is one of decomposition. When, for instance, hydrated sodium metasilicate is treated with water, the first infinitesimal portion dissolved is immediately decomposed with the formation of colloidal silica, and the process will go on until some more or less definite end-point is attained; but this presumed equilibrium is in no way determined by

the real solubility of the potassium silicate itself. J. M. Ordway made some observations on rubidium silicate.

G. W. Morey found that when anhydrous potassium silicate glass, $K_2O \cdot 2SiO_2$, is heated to about 450° with an amount of water insufficient to give complete soln. crystals are obtained resembling **potassium disilicate**, $K_2Si_2O_5$, or $K_2O \cdot 2SiO_2$, prepared by P. Niggli by heating a mixture of $K_2CO_3 + 2SiO_2$. If less silica is used, a liquid phase appears, and with more silica, unattacked quartz remains. W. Pukall obtained only the disilicate glass. G. W. Morey showed the conditions of stability of the disilicate. The crystals are optically biaxial, and negative. They are rhombic. The habit is usually tabular, and the crystals appear as pearly scales. There is a strong cleavage parallel to the c -axis, and a weaker cleavage parallel to the b -axis. Perfectly rectilinear or irregular polysynthetic twinning, resembling albite twinning, often occurs. The birefringence is low. The β -index of refraction is near 1.500. The crystals were quite solid at 1005° , and were all melted at 1025° , so that the m.p. is $1015^\circ \pm 10^\circ$. G. W. Morey later gave 1041° for the m.p., and he obtained the m.p. curve shown in Fig. 65. The molten liquid

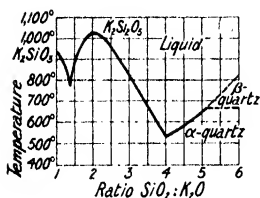

FIG. 65.—Melting-point Curve of the Binary System: K_2SiO_3 - SiO_2 .

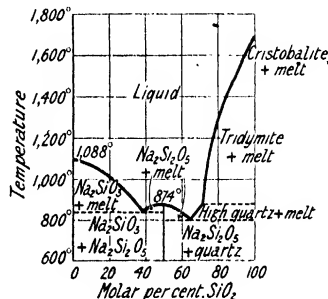

FIG. 66.—Melting-point Curve of the Binary System: Na_2SiO_3 - SiO_2 .

is very viscid, and solidifies to a glass. When a drop of water is placed on the crystals, on the stage of the microscope, they do not dissolve uniformly, but break up into thread-like forms. The solubility curves or m.p. of the binary system $K_2Si_2O_5$ - H_2O are shown in Fig. 64, and the range of stability in the ternary system K_2SiO_3 - SiO_2 - H_2O is shown in Fig. 78. G. W. Morey found that if an anhydrous glass approximating $Na_2O : SiO_2$ is heated with much water above 400° , a homogeneous hydrated glass is formed; but if the amount of water is not sufficient to give complete soln., and the temp. is 300° , crystals of **sodium disilicate**, $Na_2Si_2O_5$, are formed. W. Pukall obtained a devitrified disilicate glass. G. W. Morey and N. L. Bowen's m.p. curves are shown in Fig. 66. The m.p. of the disilicate is 875° . According to G. W. Morey, the rhombic crystals usually appear in the form of scales with a pearly lustre; and micaceous cleavage. The extinction is parallel, and the optical character negative. The indices of refraction are $\alpha=1.504$; $\beta=1.514$; and $\gamma=1.518$.

G. W. Morey found that when an anhydrous alkali silicate glass is heated with water, the product obtained depends on the temp. and press., on the amount of water present, and on the ratio $R_2O : SiO_2$. If a glass, $K_2O : SiO_2$, is heated with an equal weight of water at 400° , the product is a clear, homogeneous, hydrated glass; but if half the proportion of water be used with glasses ranging from $K_2O : SiO_2$ to $K_2O : 5SiO_2$, at 200° - 400° , the product is a mixture of the hydrated glass and crystals of **potassium hydrosilicate**, $KHSi_2O_6$, or $K_2O \cdot H_2O \cdot 4SiO_2$. The crystals can be freed from the adherent glass by leaching with hot water, without affecting the sharpness of the crystal angles. The crystals belong to the

rhombic system. The habit varies, exhibiting elongated forms parallel to the vertical axis, and tabular forms. These sometimes occur side by side. W. Pukall inferred that because plates and needles were present in one of his preparations, two different compounds were present. This by no means follows. The identification depends on measurements of the optical constants, etc. Cleavage is well developed, and parallel to the elongation; twinning is common; and the optic axial angle is 69.5° . The biaxial crystals are positive. The refractive indices are $\alpha=1.480$ – 1.495 and $\gamma=1.530$ – 1.535 . The higher numbers are probably more correct. The crystallographic properties resemble those of a hydrated potassium silicate reported by C. Friedel and E. Sarasin in 1881. The sp. gr. is 2.417 ± 0.002 at $15^\circ/4^\circ$. The crystals are not readily affected by water even when kept at 100° for several hours; they are decomposed when heated with dil. hydrochloric acid leaving a birefringent residue containing only silica and water—a similar residue has been described by F. Rinne. The vap. press. of the water is very slight since the crystals can be heated in air to 350° without loss, but at 450° , the loss is appreciable. G. W. Morey also obtained evidence of **monohydrated potassium disilicate**, $K_2Si_2O_5 \cdot H_2O$, on the solubility curves, Fig. 64, and in the ternary system, Fig. 65. This compound is decomposed by water below 280° , and at 405° , it passes into the anhydrous salt. The crystals occur in rounded forms, rarely showing crystal faces. The crystals are biaxial and positive, and have a small axial angle, and high birefringence. They dissolve completely in water.

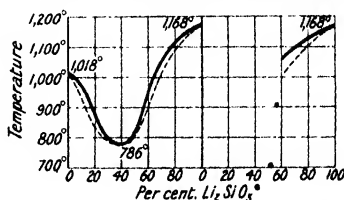

W. Pukall obtained what he regarded as *dihydrated potassium disilicate*, $K_2Si_2O_5 \cdot 2H_2O$, by crystallization from an aq. soln. of the metasilicate; he also reported *potassium dihydro-tetra-silicate*, $K_2H_2Si_4O_{13}$, *potassium dihydrohexasilicate*, $K_2H_2Si_6O_{19}$, and *potassium dihydro-octosilicate*, $K_2H_2Si_8O_{25}$, to be formed as insoluble zeolites by the action of superheated steam on the glasses. G. W. Morey could not verify these observations. W. K. Sullivan obtained *tetraerohydrated potassium pentasilicate*, $K_2O.5SiO_2.14H_2O$, by leaving a soln. of potassium silicate in contact with carbon dioxide under press. for a few months. The white crust which adhered to the gummy silica was removed, and dried in contact with frequently renewed filter-paper. The excess of potassium carbonate was removed by allowing the crust to stand on filter-paper alongside a dish of water under a bell jar; the paper was frequently renewed. In a few months, the potassium carbonate was all removed, and the residue was dried at 60° in a current of air.

J. W. Dohereiner,¹⁰ and C. L. Bloxam studied the action of silica on heated mixtures of sodium and potassium carbonates. J. Regnaud reported that the stickiness of potash water-glass is reduced when mixed with soda water-glass. B. von Ammon and J. M. Ordway said that the sodium and potassium silicates do not form a *potassium sodium silicate*. J. Lemberg studied the action of a soln. of sodium silicate on one of potassium salts, and conversely; C. G. C. Bischof, the effect of sodium chloride on a soln. of potassium silicate; and J. Lemberg, the action of potassium chloride or nitrate on a soln. of sodium silicate, and of sodium nitrate on a soln. of potassium silicate.

O. Schott obtained glasses by fusing mixtures of sodium and lithium carbonates and silica. R. C. Wallace found that with mixtures of sodium and lithium silicates, no *sodium lithium silicate* is formed, but an unbroken series of mixed crystals is produced—Fig. 67; while with lithium and potassium silicates no evidence of the formation of a *potassium lithium silicate*

was obtained—Fig. 68. No crystallization occurred with mixtures containing less than 50 per cent. of lithium silicate; and only when lithium silicate exceeded 60 per cent. were mixed crystals formed. For *potassium nitratosilicate*, *vide infra*, silver silicates.

§ 24. Copper, Silver, and Gold Silicates

Copper oxide and silicic acid do not exhibit a marked affinity for one another, and stable compounds are not common. Copper silicates do not occur abundantly in nature. Copper oxide dissolves in fused silicates producing blue or green glasses. The alkali silicate glasses tinted by copper are blue.¹ The coloration of glass by copper has been discussed by P. Ebpell, P. Hautefeuille, V. Auger, M. Pettenkofer, A. Lecrenier, F. Wöhler, E. Frémy and G. Clémendot, P. Zulkowsky, F. Knapp, H. S. Washington, H. Hecht, L. Jatschewsky, etc. The coloration of glass and glazes a ruby red, the so-called Chinese red, rouge flamme, rouge flambé, sang de bœuf, etc., has been discussed by C. Paal and W. Leuze, J. C. M. Garnett, F. Knapp, M. Pettenkofer, P. Zulkowsky, C. E. Guignet and L. Magne, R. Schwarz, H. A. Seger, C. Lauth and G. Dutailly, W. Spring, H. le Chatelier and G. Charpy, C. Otsuki, L. Franchet, W. H. Zimmer, etc. The general results indicate that the coloration is produced by colloidal copper in the same way that gold-ruby colours are produced by colloidal gold (*q.v.*). P. Zulkowsky considered that it is necessary to assume the existence of two modifications of copper to explain why strongly heated copper-ruby glass is colourless when rapidly cooled. The colourless variety is presumably dissolved copper, the red variety is copper which has had time to separate. P. Zulkowsky found that a blue soln. of an ammoniacal cupric salt is not decolorized by powdered copper-ruby glass, and hence inferred that the copper is not present in the metallic form. He assumed that sufficient copper would be exposed or accessible to the reagent under these conditions. It would not be surprising if he is wrong when it is remembered that copper-ruby glass has 0.1 per cent. of copper. For colloidal copper silicates, *vide supra*, water-glass.

According to M. Philips, when an alloy of copper and silicon is exposed to moist air for eight days, a black oxidized layer is formed; and by using the alloy as anode in an alkaline soln. of potassium tartrate, a black deposit is formed which, when washed with alcohol and ether, and dried, has a composition corresponding with impure **cuprous orthosilicate**, Cu_2SiO_4 . J. L. Jarman and J. F. MacCaleb investigated an acidic slag which was supposed to contain cuprous silicate. J. N. von Fuchs,² and A. I. Walcker obtained a bluish-green precipitate by adding a cupric salt soln. to one of water-glass, and the colour is retained when the soln. is boiled. Observations on the product were made by G. Barth, A. Keim, and R. Dollfus. O. Löw said that the precipitate is soluble in a conc. aq. soln. of potassium hydroxide, and J. Schröder, that it is insoluble in pyridine. According to E. Jordis and W. Hennis, the reaction between copper sulphate and sodium silicate in aq. soln. does not occur according to the equations which can be written for them. If the reagents are mixed in eq. proportions an acid liquid is obtained which contains silicic acid. The amount of metal in the filtrate varies independently of the reaction in the liquid. In the presence of much alkali, the metal dissolves together with the silicic acid. If an excess of either reagent is added, the proportion which passes into the filtrate increases from a minimum with the excess. The hydrated silicates are blue, the anhydrous silicates are green. M. Rülger obtained no *copper orthosilicate* by heating a mixture of the constituent oxides at $900^\circ\text{--}1000^\circ$. C. N. Otin found that it is impracticable to make a thermal analysis of the binary system cuprous oxide-silica, on account of oxidation to cupric oxide, and a ternary system is thus formed. Basic mixtures were formed containing crystals of cuprous oxide, together with a eutectic. The thermal results, together with the determinations of density, indicate that several silicates are formed, the compositions of which are uncertain.

H. Schiff reported a green precipitate to be formed when an alkali silicate is added to a soln. of a cupric salt. Most of the copper oxide dissolves in aq. ammonia, and when the residue is dried, it furnishes an amorphous powder with a composition of **copper diammino-disilicate**, $\text{CuO} \cdot 2\text{SiO}_2 \cdot 2\text{NH}_3$. C. Simmonds prepared by precipitation a product with the composition of a *sodium cupric silicate*, $3\text{Na}_2\text{O} \cdot 17\text{CuO} \cdot 27\text{SiO}_2 \cdot 20\text{H}_2\text{O}$, and he examined its reduction when heated to redness in a stream of hydrogen.

According to A. Scacchi,³ *neocyanite*, a sublimation product of Vesuvius, is probably **cupric metasilicate**, CuSiO_3 . It was also described by F. Zambonini. By treating a soln. of water-glass with copper sulphate, W. Pukall obtained a hydrated mixture of cupric metasilicate and cupric hydroxide, $3\text{CuSiO}_3 \cdot \text{Cu}(\text{OH})_2 \cdot 4\text{H}_2\text{O}$. H. Schwarz and G. A. Mathis obtained a product agreeing with $\text{CuSiO}_3 \cdot \text{H}_2\text{O}$ by adding the proper proportion of a 0.25 per cent., soln. of sodium metasilicate to a 2 per cent. soln. of pentahydrated cupric sulphate; and if the soln. contained a little *N*-NaOH, $\text{CuSiO}_3 \cdot 2\text{H}_2\text{O}$ was obtained. They also made mono- and dihydrated **cupric amminometasilicates**, $\text{CuSiO}_3 \cdot \text{H}_2\text{O} \cdot \text{NH}_3$; and $\text{CuSiO}_3 \cdot 2\text{H}_2\text{O} \cdot \text{NH}_3$, as well as dihydrated **cupric diamminometasilicate**, $\text{CuSiO}_3 \cdot 2\text{H}_2\text{O} \cdot 2\text{NH}_3$, stable below -16° .

W. T. Schaller described crystals of what he called *shattuckite* from the Shattuck Arizona Copper Co.'s mine at Bisbee. According to F. Zambonini, the composition, $\text{CuO} \cdot \text{SiO}_2 \cdot \frac{1}{2}\text{H}_2\text{O}$, **hemi-hydrated cupric metasilicate**, resembles that of the mineral *plancheite*. W. T. Schaller also found crystals of **monohydrated cupric metasilicate**, $\text{CuSiO}_3 \cdot \text{H}_2\text{O}$, in the same mine; and the mineral was called *bisbeeite*. A. F. Rogers found it in a copper mine in the Grand Canyon, Arizona. The mineral belongs to the rhombic system. Both minerals are blue. E. S. Larsen gave for the refractive indices of bisbeeite, $\alpha=1.615 \pm 0.01$, $\beta=1.625 \pm 0.01$, and $\gamma=1.71 \pm 0.01$. A. F. Rogers considered this sample to be impure because he obtained for sodium light $\alpha=1.589$, $\beta=1.620$, and $\gamma=1.649 \pm 0.001$; W. T. Schaller's values are α or $\beta=1.59$ and $\gamma=1.65$. The birefringence, $\gamma-\alpha=0.060 \pm 0.002$; the extinction is parallel; and the optical character is positive. The mineral is pleochroic, being

deep blue in the γ -direction; pale bluish-green in the β -direction; and neutral in the α -direction. Fragments of the mineral are soluble in molten sodium metaphosphate. The colloidal mineral from Copper Mountain, Alaska, described by A. F. Rogers, was called *cornuite*, and a similar mineral described by H. Buttgenbach from Katanga, Belgian Congo, was called *katangite*.

In 1800, B. F. J. Hermann, before the St. Petersburg Academy, described a mineral which he had obtained indirectly from Achir or Aschir Mahméd, who found it near Semipalatna. The mineral was named *achirite* or *aschirite*. The account was published in 1802, but meanwhile, R. J. Haüy had published an account of the mineral and named it *diopase*—from $\delta\alpha\iota$, through; $\delta\pi\rho\acute{\alpha}\zeta\omega$, to see—because the cleavage directions could be seen by looking through the crystal.

The mineral was mentioned by J. J. Ferber, J. C. Delamétherie, and A. G. Werner, and they considered it to be a kind of emerald coloured with copper—*Kupferemerald*. F. Mohs called it *Smaragdochalcite*. Later descriptions were made by C. A. S. Hofmann, F. Sandberger, E. S. Dana, M. Bauer, N. von Kokscharoff, etc. The mineral occurs associated with limestone and quartz in the Kirghese Steppes, Malaja Urjumskaia (Russia), and was described by C. D. Schangin, N. von Kokscharoff, A. Breithaupt, M. Websky, A. Lévy, G. A. Kenngott, A. Lésaulx, R. Maack, P. W. Jeremejeff, A. des Cloizeaux, and H. Credner; at Rezbaria (Hungary), and was described by J. A. Krenner; near Comba in the French Congo, and was described by E. Jannetaz, and A. des Cloizeaux; (Africa); in Chili and Peru, and was described by G. vom Rath, M. Bauer, and C. A. Burghardt; at Clifton, Graham Co. (Arizona), and was described by E. R. Hills, and G. F. Kunz, and at Riverside, Pinal Co., when it was described by W. B. Smith.

The mineral was analyzed by L. N. Vauquelin, H. Hess, A. Damour, M. Henglein, F. Zambonini, G. Tschermak, etc. The data agree with the formula, $\text{CuSiO}_3 \cdot \text{H}_2\text{O}$. C. F. Rammelsberg regarded the mineral as *cupric dihydro-orthosilicate*, CuH_2SiO_4 , because the combined water is not expelled below 400° . G. Tschermak first represented it as a metasilicate, $\text{HO} \cdot \text{Cu} \cdot \text{SiO}_3 \cdot \text{H}$, but later adopted the orthosilicate hypothesis. F. W. Clarke gave the graphic formula: $\text{HCu} \equiv \text{SiO}_4 \cdot \text{Cu} \cdot \text{H}_2\text{SiO}_4 \cdot \text{Cu} \cdot \text{H}_2\text{SiO}_4 \cdot \text{Cu} \cdot \text{SiO}_4 \equiv \text{H}_3$. F. Zambonini found that the water begins to be evolved at 95° , and the dehydration curve is continuous; at 478° , a little still remains. There is a slight change in colour at 398° . He represents the mineral as *hydrated cupric metasilicate*, $\text{CuSiO}_3 \cdot \text{H}_2\text{O}$. A. C. Becquerel synthesized the mineral by the action of soln. of cupric nitrate and potassium silicate separated by parchment paper: $\text{K}_2\text{SiO}_3 + \text{Cu}(\text{NO}_3)_2 + \text{H}_2\text{O} = \text{CuSiO}_3 \cdot \text{H}_2\text{O} + 2\text{KNO}_3$.

A. Breithaupt found that the columnar emerald-green crystals belong to the rhombohedral system, and have the axial ratios $a : c = 1 : 0.53417$. The crystals were also measured by M. Websky, A. Lévy, G. A. Kenngott, N. von Kokscharoff, H. Credner, M. Bauer, E. Jannetaz, A. des Cloizeaux, J. A. Krenner, etc. The fracture is conchoidal. The sp. gr., according to A. Breithaupt, is 3.270–3.301; and, according to G. A. Kenngott, 3.314–3.348. The hardness on Mohs' scale is 5. R. Cusack gave 1171° , and A. L. Fletcher 1221° for the m.p. of diopase. The pleochroism is feeble; and the double refraction strong and positive. W. H. Miller gave for the indices of refraction, $\omega = 1.667$, and $\epsilon = 1.723$; A. F. Rogers gave for cornuite, 1.549. A. Ehringhaus and H. Rose compared the dispersion and double refraction of the orthosilicates of copper, beryllium, and zinc with their mol. wts. W. Hankel found that the crystals are pyroelectric, and when cooled, both ends of the principal axis are negative, and the surfaces positive. J. Lemberg studied the microchemical reactions. When treated with hydrochloric or nitric acid, gelatinous silica is formed. According to A. Damour, a soln. of potassium hydroxide does not attack diopase, but with a soln. of ammonia and ammonium carbonate, a blue soln. is formed. C. Matignon and G. Marchal examined the corrosive action of water on diopase in the presence of carbon dioxide under 10 atm. press. during ten years. C. Simmonds examined the reduction of diopase when heated to redness in a stream of hydrogen.

In the third century B.C., the term *chrysocolla*—from $\chi\rho\upsilon\sigma\acute{\alpha}\varsigma$, gold; $\kappa\acute{\omicron}\lambda\lambda\alpha$,

glue (solder)—was applied by Theophrastus in his *Περὶ λίθων* (4. 26) to a green stone containing copper, and it appears to have been used in soldering gold; the same name has been applied to borax, also used for a similar purpose. The mineral was also mentioned by Pliny, who, in his *Historia naturalis* (33. 86, 93), applied the term to a number of different minerals including a copper carbonate. Cyprus was named as a prominent locality. In his *De materia medica*, Dioscorides said that the best chrysocolla had a leek-green or prase colour.

G. Agricola, J. G. Wallerius, and A. Cronstedt called it *Berggrün*, *caruleum montanum*, and *viride montanum*. Hence the terms *mountain blue*, *mountain green*, etc. A. G. Werner called it *Kupfergrün*. Both chrysocolla and an earthy variety of copper carbonate were included in these terms from the sixteenth to the eighteenth centuries by A. Estner, A. G. Werner, and R. J. Haüy. The last-named, however, called it *cuirre hydrosilicéuse* in 1820; and M. H. Klaproth argued that the silica in chrysocolla is not merely mixed with the copper oxide, because the two constituents form a chemical compound. J. F. John made a similar observation as a result of his analysis of a specimen of Siberian *Kieselkupfer*. J. F. L. Hausmann called the mineral *Kieselkupfer*, and C. C. Leonhard, *Kieselmalachit*. P. Berthier's specimen of chrysocolla from Somerville, New Jersey, was for a time called *somervilleite*. The so-called *Kupferblau* of G. Rose contains some carbonate as impurity. *Kupferpecherz* or *melanoschalite*, analyzed by G. A. Rönig and by W. Lindgren and W. F. Hillebrand, contains appreciable quantities, and have been called *cupric carbonate-silicates*. The *asperolite* of R. Hermann, named on account of its brittleness, was found at Taghik, Russia, and it was considered to be trihydrated copper metasilicate, $\text{CuSiO}_3 \cdot 3\text{H}_2\text{O}$, or dihydrated copper dihydro-orthosilicate, $\text{H}_2\text{CuSiO}_4 \cdot 2\text{H}_2\text{O}$. He considered it a member of the series of hydrated cupric silicates diopside, chrysocolla, asperolite. The *Kupferpecherz* of C. A. S. Hofmann is almost black in colour; it was described by A. Damour, C. F. Rammelsberg, and F. von Kobell, and is regarded as a mixture of limonite and chrysocolla; similar remarks apply to the *Hepatinerz* of A. Breithaupt.

The mineral has been reported from various localities. G. Rose, W. Haidinger, C. Haerwald, R. J. Haüy, P. W. Jeromeff, J. R. Blum, and C. F. Rammelsberg mentioned its occurrence at Bogoslovsk, Niznij-Tagil, and Altai, in Russia; T. Scheerer, at Strömsheien in Norway; A. Breithaupt, in Baden; C. W. von Gumbel, at Kupferberg in Bavaria; E. S. Dana, and J. C. Ullmann, in Nassau; A. Frenzel, at Schneeberg in Saxony; M. Wolsky, and H. Traube, in Silesia; P. Herter, V. R. von Zepharovich, and K. F. Peters, at Rochlitz in Bohemia; G. Sillem, K. F. Peters, J. R. Blum, and V. R. von Zepharovich, at Libenthen in Hungary; L. von Köchel, and E. Fugger, in Salzburg; G. Tschermak, and L. Liebenow and J. Vorhausser, at Falkenstein and Schwatz in Tyrol; G. A. Kennigott, in Switzerland; G. Roster, and A. E. Delesse, in Italy; D. F. Wiser, G. Freda, and J. R. Blum, at Nicolosi, and Lipari, in Sicily; J. Berthier, at Canavallès, France; R. P. Greg and W. G. Lettsom, on the copper mines of Cornwall, England; A. Knop, P. Groth, and G. Gurich, at Namaqualand in Africa; G. T. Bowen, P. Berthier, and A. Dufrénoy, at Somerville in New Jersey; J. R. Santos, a specimen from Utah; G. F. Kunz, F. P. Dunnington, R. Robertson, and J. W. Mallet, in Gila Co., Arizona; G. A. König, in Denver, Colorado; L. C. Beck, at Franklin, New Jersey; E. Jannettaz, and W. M. Hutchings, in California; A. Breithaupt, at Zimapan, Mexico; C. A. Burghardt, in Peru; I. Domeyko, in Chile; and A. L. Sack, A. Liversidge, and J. R. Blum, in South Australia, and New South Wales. Analyses have been reported by J. R. Blum, T. Scheerer, F. von Kobell, C. F. Rammelsberg, R. Hermann, G. Freda, J. R. Santos, F. P. Dunnington, R. Robertson, J. W. Mallet, E. Jannettaz, W. M. Hutchings, I. Domeyko, N. Pollegri, W. Lindgren and W. F. Hillebrand, H. F. Keller, E. Manasse, F. Field, P. Berthier, L. C. Beck, G. T. Bowen, P. Herter, E. S. Dana, A. Damour, T. Thomson, J. C. Ullmann, M. H. Klaproth, etc.

The analyses show that idealized chrysocolla is **dihydrated copper metasilicate**, $\text{CuSiO}_3 \cdot 2\text{H}_2\text{O}$; and, excepting for the water content, it has the same ultimate composition as diopside. As is usual with colloidal minerals, the composition varies much owing to impurities. The silica is probably derived from the decomposition of other minerals, and an excess appears in many analyses. Besides free silica, oxides of copper, iron, and manganese may be present, and this would change the colour to a brown or black. Some copper carbonate and sulphate may be present, as well as oxides of lead, antimony, arsenic, etc. C. G. C. Bischof suggested that copper silicates have been formed in nature by the action of silicates of the alkalis, alkaline earths, or magnesia from the weathering of silicate rocks on soln. of copper salts from the oxidation of copper pyrites. He also found that copper silicate is decomposed by carbonated waters, forming copper carbonate. E. S. Dana mentioned specimens of chrysocolla from Chili in which the interior was malachite.

T. Scheerer found chrysocolla associated with feldspar, and assumed it to have been formed by the action of cupric sulphate on that mineral. The analyses of different samples, however, agree with the ratios $\text{Cu} : \text{Si} : \text{H}_2\text{O} = 1 : 2 : 2.6$ (Lipari), $1 : 2 : 2.3$ (Boleo), and $1 : 1 : 2$ (Nicolosi). H. F. Keller's analysis of a sample from Huixtintipa corresponds with $\text{CuH}_2(\text{SiO}_3)_2 \cdot \text{H}_2\text{O}$. P. Groth holds that chrysocolla may occur mixed with the *copper aluminosilicate*, $\text{CuAl}_2\text{Si}_2\text{O}_8$. Chrysocolla occurs both in the colloidal and crystalline states, and it is coloured blue or green. The colloidal nature is in agreement with the different views which have been reported as to the proportion of combined water. A. F. Rogers regarded the crystalline form as a metacolloid, i.e. a microcrystalline substance of colloidal origin. A. F. Rogers and F. H. Probert regard the variable composition as due to the adsorption of magnesia, lime, and other oxides. A. Breithaupt gave 2.560 for the sp. gr.; E. Jannetaz, 2.272; R. Hermann, 2.306; and T. Scheerer, 3.317. The sp. gr. of specimens with a low proportion of impurity ranges from 2.0–2.2. The hardness is between 2 and 4 on Mohs' scale. Chrysocolla is decomposed by acids with the separation of pulverulent silicic acid; and not gelatinous silicic acid as in the case of diopside. C. Simmonds examined the reduction of chrysocolla in a stream of hydrogen at a red heat. E. Dittler said that chrysocolla readily adsorbs aniline dyes. E. Puxeddu and E. Mañica found the mineral from Bena de Padru to be radioactive.

A. Lacroix⁵ found a variety of chrysocolla at Mondouli in the French Congo, and he named it *plancheite*. Its composition approximated $15\text{CuO} \cdot 12\text{SiO}_2 \cdot 5\text{H}_2\text{O}$. The formula has some analogies with that of ganomalite. It can be regarded as a basic copper metasilicate, $\text{H}_2\text{Cu}_2(\text{CuOH})_4(\text{SiO}_3)_{12}$. The sp. gr. is 3.36. M. Henglein noted the occurrence of this mineral at Guchab, S.W. Africa. N. von Nordenskjöld described a blue mineral, *demidovite*, or *demidoffite*, found by A. von Demidoff in Nizhny-Tagil (Ural). It appears to be a silicophosphate, a mixture of a silicate and phosphate, or a mixture of opal and phosphate. It was also examined by N. von Kokcharoff. The analysis indicates 31.55 per cent. SiO_2 ; 33.14, CuO ; 0.53, Al_2O_3 ; 1.53, MgO ; 23.03, H_2O ; 10.22, P_2O_5 . The sp. gr. is 2.25, and the hardness 2. R. P. Greg obtained a similar mineral in Cornwall. D. M. Kramberger described a mineral, *pilarite*, obtained at Pilar in Agram, having the composition $\text{CaCu}_2\text{Al}_2\text{Si}_{12}\text{O}_{38} \cdot 24\text{H}_2\text{O}$; sp. gr. 2.62; and hardness 3. It may be a mixture of copper aluminosilicate, etc. According to F. Cornu and M. Lazarevic, both demidovite and pilarite are colloidal chrysocolla with adsorbed matters. A. d'Ambrosio described a blue, compact, porcelain-like *nuova varietà di crisicolla* which he called *traversoute*, after G. B. Traverso. It was found at Arenas, Sardinia, and its composition corresponded with $2(\text{Cu,Ca})\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 12\text{H}_2\text{O}$. The index of refraction of the isotropic mineral is 1.565. A. F. Rogers, and S. G. Gordon described samples from the Grand Canyon which are probably *cyanotrichite*, a blue mineral occurring in needle-like crystals described by E. S. Larsen with $\alpha = 1.588$, $\beta = 1.167$, and $\gamma = 1.655$.

If a piece of silver be heated in contact with glass or glaze, below the softening temp. of either, the silicate acquires a yellow colour owing to the diffusion of the metal into the solid. The diffusion of silver in glass has been discussed by A. Heydweiller and F. Kopfermann,⁶ E. Warburg, G. Schulze, etc. Glass coloured with colloidal silver, analogous to gold ruby glass, is blue. J. S. Stas also showed that finely divided silver combines with glass when heated in a current of air to near its softening temp., and that silicates and silica are attacked by the molten or vaporized metal. Porcelain is coloured yellow or yellowish-brown when heated with silver. J. J. Berzelius showed that silver introduced as oxide also dissolves in fused silicates, forming yellow glasses; and he said that when the precipitate obtained by adding aq. ammonia to a soln. of silver fluosilicate, is treated with an excess of ammonia, *silver silicate* is formed. For colloidal silver silicates, *vide supra*, water-glass. E. Jordis found that when sodium silicate is fused in a silver crucible, the metal is attacked, and when the product is extracted with water, a brown voluminous mass remains which becomes black when treated with an excess of water. It contains silver and soda in the ratio $\text{Ag} : \text{NaOH} = 0.001296 : 1$. If silicic acid is added, a brown silver silicate is formed. J. D. Hawkins said that if a soln. of silver nitrate be treated with sodium silicate, a citron-yellow pre-

precipitate is formed, which becomes darker in colour when dried. Analyses show that it contains a little more silica (as impurity) than corresponds with **silver metasilicate**, Ag_2SiO_3 . It is readily decomposed by acids, and is completely soluble in aq. ammonia. It can be heated without decomposition, but, at a red heat, it decomposes into silica, silver, and oxygen. W. Pukall claimed to have made a metasilicate by heating an intimate mixture of silicic acid and silver oxide in theoretical proportions. The dark yellow crystalline product is readily attacked by nitric acid. R. Schwarz and G. A. Mathus worked with dil. soln., and obtained a precipitate of dihydrated silver metasilicate, $\text{Ag}_2\text{SiO}_3 \cdot 2\text{H}_2\text{O}$; and they converted this into dihydrated **silver diamminometasilicate**, $\text{Ag}_2\text{SiO}_3 \cdot 2\text{H}_2\text{O} \cdot 0.2\text{NH}_3$.

According to G. Rousseau and G. Tite, when silver nitrate is heated with a small quantity of water and fragments of marble in sealed glass-tubes at 180° – 300° for many hours, deep ruby crystals are obtained, adhering strongly to the sides of the tube. They correspond with **silver dinitratotriorthosilicate**, $2\text{AgNO}_3 \cdot 3\text{Ag}_2\text{SiO}_4$, or $7\text{Ag}_2\text{O} \cdot 3\text{SiO}_2 \cdot \text{N}_2\text{O}_5$. A similar product is obtained if finely divided silica is added to the contents of the tube, and in this case the crystals do not adhere to the glass. Silver oxide may be used in place of calcium carbonate, but the excess is difficult to separate at the end of the operation. *The same product is obtained in smaller crystals by heating silver nitrate with silica at 350° – 440° . Silver nitratosilicate forms short, ruby prisms showing longitudinal extinction in parallel light. When heated to dull redness, the crystals intumescence with evolution of nitrogen oxides, leaving a residue of metallic silver and the silicate, Ag_2SiO_3 . The nitratosilicate is easily soluble in dil. nitric acid, but after some time, and especially on heating, silica separates. Hydrochloric acid decomposes the compound immediately with the separation of silver chloride. Ammonium chloride also decomposes it, and the soln. smells of ammonia, but *nitratosilicic acid* could not be isolated. A soln. of potassium chloride soln. is without action even at 100° , but potassium iodide yields silver iodide and *potassium nitratosilicate*, the latter separating in long needles when the filtrate from the silver iodide is conc. in a vacuum.

For the coloration of glass with gold, *vide* 3. 23, 11. According to P. P. von Weimarn,¹ if 0.1–1.0 per cent. soln. of sodium chloraurate and sodium silicate are mixed, a clear soln. of, possibly, *auric silicate* is obtained. This gradually develops a reddish colour, and, changing slowly, finally becomes blue. Coagulation commences after several months, and the microscopic examination of the coagulum has shown a close similarity in structure with that presented by the gold in auriferous quartz. H. Rose assumed that the colourless glass which becomes ruby-red when reheated contains gold silicate, and that the red colour occurs when the silicate changes to red oxide. Had he said that the red colour is due to the separation of ultra-microscopic particles of gold, many would have agreed with him to-day.

§ 25. The Silicates of the Alkaline Earths

P. Berthier¹ tried to make a definite silicate by fusing a mixture of lime and silica, and separating the free lime by washing. This method led him to the formula $2\text{CaO} \cdot 3\text{SiO}_2$ for the product; L. E. Rivot, to $2\text{CaO} \cdot \text{SiO}_2$; and E. Landrin, to $4\text{CaO} \cdot 3\text{SiO}_2$. Assuming that the mixture was completely fused, the anhydrous basic silicates are partially decomposed by water, and the hydrated silicates are progressively decomposed by the washing with water. N. G. Sefström heated various mixtures of quartz and marble in carbon crucibles in a blast furnace, and obtained products which were represented by the older chemists as definite calcium silicates—e.g. calcium orthosilicate, $2\text{CaO} \cdot \text{SiO}_2$; calcium metasilicate, $\text{CaO} \cdot \text{SiO}_2$; calcium sesquisilicate, $2\text{CaO} \cdot 3\text{SiO}_2$; calcium mesodisilicate, $\text{CaO} \cdot 2\text{SiO}_2$; and calcium paratrisilicate, $\text{CaO} \cdot 3\text{SiO}_2$ —although there was little or no evidence that the products were chemical individuals. Similar remarks apply to the silicates reported by E. Martin—viz. $2\text{CaO} \cdot 5\text{SiO}_2$; $8\text{CaO} \cdot 5\text{SiO}_2$; $10\text{CaO} \cdot 5\text{SiO}_2$; $10\text{CaO} \cdot 5\text{SiO}_2 \cdot 2\text{H}_2\text{O}$; $13\text{CaO} \cdot 5\text{SiO}_2$; and $2\text{CaO} \cdot 5\text{SiO}_2 \cdot 3\text{H}_2\text{O}$. W. S. Patterson and P. F. Summers discussed the effect of additions of alumina, and oxides of copper, zinc, iron, and magnesium on the fusibility of lime silicate slags.

Observations on the fusibility of mixtures of silica and calcium oxide were made by A. Petzholdt, H. Philippi, W. A. Lampadius, P. Berthier, N. G. Sefström, F. Gredt, W. Heldt, G. Oddo, E. Jordis, O. Schott, R. Rieke, and A. J. Rossi.

J. W. Cobb noted that the reaction begins below the m.p. of either component. O. Boudouard observed three maxima and four eutectics on the fusion curve. The maxima corresponded with calcium orthosilicate, calcium metasilicate, and tricalcium silicate. A. L. Day and E. S. Shepherd showed that under normal conditions, combinations are formed at temp. below the m.p. provided the constituents are finely powdered and adequately mixed. They found that silica and calcium carbonate (1 : 1) begin to react at 800°, and the reaction is nearly complete at 1400°; and mixtures of silica and calcium sulphate (between 1 : 3 and 3 : 1) react between 1005° and 1010°. J. A. Hedvall detected signs of a reaction between precipitated silica with calcium oxide at 1000°, and silicate formation at 1400°; and with barium oxide at 900°. E. Tischler found that at a press. of 25 atm. in steam it is not possible to effect the union of eq. proportions of lime and silica, but at 200 atm. very little escapes combination; and the compound formed is $\text{CaSiO}_3 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, but the proportion of water varies a little. H. O. Hofman made observations on the temp. of formation; and R. Akerman measured the heats of solidification, Q , of some calcium silicate mixtures. If θ° be the m.p.; C cals., the sp. ht. between 0° and θ° ; L , the latent heat of fusion, $Q = C\theta + L$. D. Balareff found that the presence of water, and of traces of hydrogen chloride or sulphide vap. favours the reaction between silica and calcium oxide; while air, hydrogen, and carbon dioxide also favour the reaction. It is assumed in some cases that the gas forms a surface skin of, say, sulphide or chloride, which fuses easily and brings the two materials in better contact. In other cases, the surface mols. are loosened by the adsorption of the gas, and the effect is comparable with softening or melting.

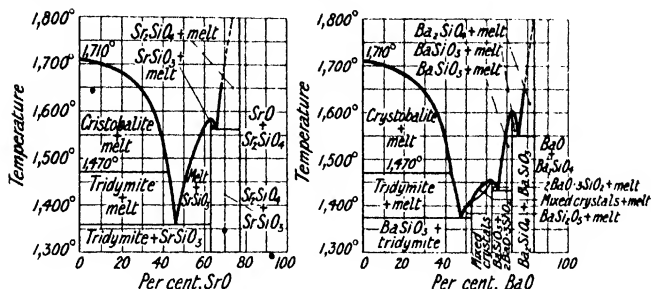

The thermal diagram of mixtures of calcium oxide and silica has been developed by A. L. Day and co-workers, C. Doelter, G. A. Rankin and co-workers, P. Niggi, and J. B. Ferguson and H. E. Merwin. This work is summarized in Fig. 70. Calcium forms at least four definite silicates: the orthosilicate, Ca_2SiO_4 ; the metasilicate, CaSiO_3 ; the orthodisilicate, $\text{Ca}_3\text{Si}_2\text{O}_7$; and the basic silicate, Ca_3SiO_5 . In addition, the ortho- and meta-silicates exhibit crystalline modifications. The mutual relations of these different compounds are illustrated in the equilibrium diagram, Fig. 70. S. G. Gordon reported the occurrence of the αCaSiO_3 - $\text{Ca}_3\text{Si}_2\text{O}_7$ eutectic at Spartanburg, S.C. The compositions and temp. of critical points are summarized in Table XIII, where the temp. marked with an asterisk are incongruent m.p., the others are congruent.

P. Berthier tested the fusibility of various mixtures of silica with baryta and with strontia. P. Eskola's equilibrium diagrams for strontium and barium oxides with silica are shown in Figs. 69 and 70. The results are summarized in Table XIV. The m.p. in the table are all congruent. Strontium furnishes the orthosilicate, $\text{Sr}_2\text{Si}_2\text{O}_7$, and the metasilicate, SrSiO_3 , but not in polymorphic forms. Barium also furnishes one form each of the orthosilicate, Ba_2SiO_4 ; the metasilicate, BaSiO_3 ;

the mesosilicate, BaSi_3O_8 ; and the mesotrisilicate, $\text{Ba}_2\text{Si}_3\text{O}_8$. P. Bary discussed the glassy silicates of the alkaline earths.

FIGS. 69 AND 70.—Temperature-Concentration Diagrams of the Binary Systems: $\text{SrO}-\text{SiO}_2$ and $\text{BaO}-\text{SiO}_2$.

A number of hydrated calcium silicates have been reported in nature, and some have been prepared artificially. The products obtained by the wet processes are usually variable in composition and have the character of colloids. Near the

end of the eighteenth century J. Gadolin,² and L. B. G. de Morveau precipitated alkali silicates by a calcium salt, and by treating hydrated silica with calcium hydroxide. J. N. von Fuchs stated that hydrated silica added to lime-water precipitated a white, pulverulent calcium silicate. W. Heldt observed that silicic acid mixed with milk of lime forms a hard mass. E. Landrin stated that gelatinous and dialyzed silicic acid acts on lime-water forming various hydrated calcium silicates which play a rôle in the setting of hydraulic cement. He represented the composition of the precipitate by $4\text{CaO} \cdot 3\text{SiO}_2$; L. E. Rivot, by $2\text{CaO} \cdot \text{SiO}_2$; and P. Berthier, by $2\text{CaO} \cdot 3\text{SiO}_2$. This subject was studied by H. le Chatelier, who demonstrated that products with a composition between $\text{CaO} \cdot 10\text{SiO}_2$ and $2\text{CaO} \cdot \text{SiO}_2$ can be obtained by varying the proportions of lime and silica used in their preparation, and by using a sufficient vol. of water in washing, a residue of nearly pure silica can be obtained. E. Jordis found that the action of hydrated silica on a boiling soln. of lime-water gives products of variable composition the mean of which is $0.65\text{CaO} \cdot \text{SiO}_2$. E. Jordis and E. H. Kanter did not obtain homogeneous products by heating silicic acid and calcium hydroxide in the presence of a molar soln. of calcium chloride; and when a soln. of calcium hydroxide, either alone, or in the presence of a calcium salt, and suspended silicic acid, is boiled, the calcium from the hydroxide combines with the silica, and is afterwards removed from the

compound formed, and then again combines with it to a greater extent than before. The anion of the calcium salt plays a part in the reaction. A mixture of calcium oxide or hydroxide and quartz or amorphous silica—kieselguhr—was heated under press.—20–200 atm.—in an autoclave. The tenacity of the product with calcium

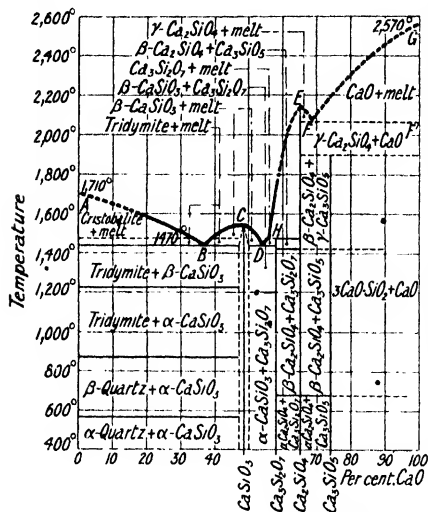

FIG. 71.—Equilibrium Diagram of Binary Mixtures of Calcium Oxide and Silica.

silicate: $3\text{CaO} \cdot \text{SiO}_2 + 4\frac{1}{2}\text{H}_2\text{O} \rightarrow 2\text{Ca}(\text{OH})_2 + \text{CaO} \cdot \text{SiO}_2 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, Fig. 71. When a mixture of milk of lime and a conc. soln. of water-glass is stirred, speedy coagulation occurs, and the mixture "sets," and it becomes crumbly if the stirring is continued. If the soln. be sufficiently dil. a voluminous precipitate of calcium silicate is formed. These phenomena were observed by J. N. von Fuchs, J. M. Ordway, etc.

F. Kuhlmann also noted that an aq. soln. of an alkali silicate is decomposed by calcium carbonate, sulphate, or phosphate, forming calcium silicate and an alkali salt. C. G. C. Bischof said that calcium carbonate does not react with hot or cold soln. of alkali silicate; J. von Liebig said that washed chalk adsorbs but a little alkali silicate from a dil. aq. soln. of water-glass; J. M. Ordway, and F. von Kobell noted that calcium carbonate decomposes a hot soln. of water-glass. A. C. Becquerel obtained stalactitic formations of calcium silicate by introducing chalk impregnated with lead or cupric nitrate into a soln. of water-glass of sp. gr. 1.074; and by separating soln. of calcium acetate and potassium silicate by means of a porous membrane, he obtained a deposit of doubly refracting crystals of calcium silicate on the membrane. C. F. Rammelsberg reported the presence of needle-like crystals of hydrated calcium orthosilicate, $3\text{CaO} \cdot 2\text{SiO}_2 \cdot \text{H}_2\text{O}$, or $\text{CaSiO}_3 \cdot \text{Ca}_2\text{SiO}_4 \cdot \text{H}_2\text{O}$, from the hearth of a Leblanc soda-ash furnace. W. Heldt reported the formation of the hydrated salts: pentahydrated calcium tripentasilicate, $5\text{CaO} \cdot 3\text{SiO}_2 \cdot 5\text{H}_2\text{O}$, by triturating a mixture of calcium hydroxide and a soln. of water-glass; and of trihydrated calcium paratrisilicate, $\text{CaO} \cdot 3\text{SiO}_2 \cdot 3\text{H}_2\text{O}$, by the action of calcium chloride on a soln. of water-glass. T. J. Pélouze, and J. Weisberg precipitated the silica as calcium silicate from a soln. of an alkali silicate by the addition of calcium chloride; W. Heldt used calcium saccharate as precipitant. E. Jordis and E. H. Kanter could not obtain evidence of the formation

hydroxide was less than if the mixture with calcium oxide was afterwards hydrated. The tenacity was greater the greater the density of the silica. Quartz reacts most slowly. The maximum tenacity was obtained with $\text{CaO} : \text{SiO}_2 = 1 : 3$, combination was not complete. With a mixture $\text{CaO} : \text{SiO}_2 = 1 : 1$, combination was complete at 200 atm. press., and the resulting silicate had the composition $\text{CaO} \cdot \text{SiO}_2 \cdot 2.34\text{H}_2\text{O}$ — vide *infra*, hydrated calcium metasilicate. E. Tischer obtained a similar product, and H. le Chatelier said that in the hydration of hydraulic cement, elongated crystals of $\text{CaO} \cdot \text{SiO}_2 \cdot 2.5\text{H}_2\text{O}$ are formed by the decomposition of the basic trical-

of definite chemical individuals by the action of calcium chloride on aq. soln. of sodium silicate, or by the action of gelatinous silica on lime-water in the presence of calcium chloride. According to A. L. Herrera, when a soln. of potassium silicate, with a sp. gr. of 1.5 or more, and containing potassium carbonate not in excess of a normal soln., is placed inside an unglazed porcelain cup, and the latter placed in calcium chloride soln. of sp. gr. 1.007, after 24 hrs., numerous very fine tubes of calcium silicate are formed on the outside of the porous cup. The surfaces of the films have a number of microscopic cells, and in some cases are formed entirely of cells.

According to H. le Chatelier,³ crystals of **calcium oxyorthosilicate**, $\text{CaO} \cdot \text{Ca}_2\text{SiO}_4$, or $3\text{CaO} \cdot \text{SiO}_2$, occurs in hydraulic cement, and the product obtained by calcining the limestone of Teil has very nearly this composition, and it is an excellent hydraulic cement. L. E. Rivot, G. Oddo, and E. Jordis mention this compound; while A. L. Day and E. S. Shepherd say that no one has isolated a definite homogeneous compound of the composition, $3\text{CaO} \cdot \text{SiO}_2$; and attempts to make it by fusing the constituents together furnish mixtures with ill-defined optical qualities. G. A. Rankin and F. E. Wright found that the compound is unstable at its m.p., and it does not occur in contact with the melt in the binary system, Fig. 71, so that it does not occur as a primary base at any point of the liquidus curve. It does, however, occur as a primary base within the ternary system, $\text{CaO} - \text{Al}_2\text{O}_3 - \text{SiO}_2$. In the formation of the compound from the mixed oxides at $1400^\circ - 1500^\circ$, the orthosilicate is first produced, and this, on longer heating, unites with free lime to produce the basic orthosilicate. It dissociates at $1900^\circ \pm 20^\circ$, forming CaO and the orthosilicate; this temp. is below that of the eutectic, 2065° , between calcium oxide and calcium orthosilicate. The basic silicate occurs in small, colourless grains about 0.3 mm. long which are apparently without cleavage; the refractive index approximates 1.715, and the birefringence is weak, not over 0.005. The grains appear to be uniaxial or biaxial with a small optic axial angle. The optical character is negative. Fine twinning lamellæ, with low extinction angles, occur on some of the grains, indicating that the crystal system is possibly monoclinic. H. le Chatelier suggested that the oxyorthosilicate and the orthosilicate are isomorphous.

The anhydrous orthosilicates.—N. G. Sefström could not fuse a mixture of two molar proportions of calcium carbonate with one molar proportion of silica in the furnaces available in his day; but G. Oddo fused the mixture in an electric furnace, and obtained a porcelain-like mass. G. Stein, H. Hanemann, W. Pukall, and V. Pöschl made observations on this subject. E. Kittl noticed that during crystallization there are 190,000 centres of crystallization per sq. cm. H. le Chatelier, C. Zulkowsky, E. Jordis, etc., noted the occurrence of crystals of **calcium orthosilicate**, $2\text{CaO} \cdot \text{SiO}_2$, or Ca_2SiO_4 , in the clinker of portland cement. A. Meyer, C. Zulkowsky, and P. Rohland suggest that two isomeric forms occur in portland cement; and the latter symbolized these hypothetical isomers:

A. Gorgeu found the orthosilicate among the products of the action of steam on a mixture of silica and calcium chloride at a high temp. F. de Lalande and M. Prud'homme, and W. Löwenstein obtained this compound by the action of heat on various mixtures of silica, lime, and calcium chloride. J. H. L. Vogt also found crystals of the orthosilicate in blast furnace slags. To emphasize its relation to the orthosilicates of the magnesium family, calcium orthosilicate is sometimes called *limeolivine*. D. A. Tschernobajeff and S. P. Wologdine estimated the heat of formation of $2\text{CaO} \cdot \text{SiO}_2$ to be 28.7 Cals.

According to A. L. Day and co-workers, the individuality of calcium orthosilicate is established by its appearance as a maximum, corresponding with a m.p. of 2080° on the equilibrium diagram, Fig. 71, and by the optical properties of the product. It crystallizes in three, possibly four, distinct forms. The α -form

here described is that designated the γ -form by A. L. Day and co-workers, while the γ -form here described is A. L. Day's α -form. The alteration is made in accord with general usage, where the form stable at the low temp. is called the α -variety. The γ -calcium orthosilicate is stable between 1410° and the m.p.; β -calcium orthosilicate is stable between 675° and 1410°; and α -calcium orthosilicate is stable below 675°. β' -calcium orthosilicate is a monotropic, unstable form. G. A. Rankin and co-workers give 1420° \pm 2° for the higher transition temp. of the γ - to the β -form. The changes are reversible so that they also give 2130° \pm 20° for the

m.p. of the γ -form; while A. L. Day and co-workers gave 2080°. O. Boudouard gave 1420° for the m.p. of the orthosilicate; R. Rieke, 1435°; and H. Philippi, 1450°. The different forms can be obtained in a metastable state at ordinary temp. by rapid cooling. As a result of the quenching, the transformations are checked for considerable intervals of time. R. Lorenz and W. Herz studied the relation between the m.p. and the transition temp.

The transformation of the β - to the α -form, in cooling, is attended by an expansion of about 10 per cent. This shatters the product to fine dust. The phenomenon is sometimes observed in the manufacture of portland cement, and is known as *dusting*. The phenomenon occurs with calcareous blast furnace slags. For this reason the form stable at ordinary temp., α -calcium orthosilicate, appears as a fine, colourless, transparent dust, prismatic in habit, with reflect cleavage along the prism axis. It usually extinguishes parallel to the direction of elongation, but occasionally there are indications of twinned forms with a small extinction angle, 3°. The sp. gr. is 2.97. The refractive indices are $\alpha=1.640 \pm 0.003$, $\beta=1.645 \pm 0.003$, and $\gamma=1.654 \pm 0.003$. The birefringence is medium, being about 0.014. The optic axial angle is 52°. The plane of the optic axes in contradistinction to the β - and γ -forms, is perpendicular to the prism axis or the direction of cleavage.

The colourless, transparent crystallites of β -calcium orthosilicate are prismatic; they have a cleavage parallel to the prism axis, and probably belong to the rhombic system. The sp. gr. is near 3.27. The least ellipsoidal axis is parallel to the prism axis, and the optic axial angle is very large. Twinning is absent, and the extinction is parallel. The refractive indices are large $\alpha=1.722 \pm 0.003$, and $\gamma=1.733 \pm 0.003$. The birefringence is medium, being about 0.01. The progressive paramorphic change of the β - to the α -form can be followed under the microscope. Soon after cooling, irregular interference colours appear as though induced by internal strains, and soon the mass resembles a crystalline aggregate of minute fibres. Towards the end of the process and, for the reason stated above, the larger masses usually disintegrate as fine powder. An unstable form, called β' -calcium orthosilicate, was once obtained by quenching an old hydrated sample from 1415°; it could not be obtained from fresh samples. It appears as fine colourless equant grains without visible cleavage. The average refractive index is very nearly the same as that of calcium oxyorthosilicate, being about 1.715, and the birefringence is very weak. Interference figures were difficult to obtain because of the fine granularity, and the weak birefringence; but the optic axial angle appears to be small or zero, and the optical character positive. The last characteristic distinguishes the β' -form from calcium oxyorthosilicate. This form appears to be monotropic, but the evidence of its existence cannot be regarded as conclusive.

Like β -Ca₂SiO₄, γ -calcium orthosilicate shows prismatic development with a good cleavage parallel with the prism axis. The crystals occur in irregular grains so intricately interwoven and twinned that a satisfactory measurement of the optical constants is difficult. Twinning is a characteristic feature and is often extremely complex. Different sets of the twinning lamellae occur intersecting at various angles, and together form an interpenetrating mass not unlike microcline or leucite. Occasionally, in a thin plate, only one set of polysynthetic twinning

lamellæ is present, and resembles a section of plagioclase twinned after the albite law. Extinction angles were noted as high as 18° , though smaller angles appear more frequently. The crystals are either monoclinic or triclinic—probably the former. The sp. gr. is near 3.27 ; and the hardness between 5 and 6. The refractive indices are approximately $\alpha = 1.714 \pm 0.003$, $\beta = 1.720 \pm 0.004$, and $\gamma = 1.737 \pm 0.003$; the birefringence is about 0.02 ; and the optical character is positive. The optic angle is about 180° , and the plane of the optic axes is nearly parallel with the direction of elongation of the crystals.

The α -form is readily distinguished from β - and γ -forms by its low refractive index, its optical character, optic axial angle, and the position of the plane of the optic axis to the prism axis; while the β -form is distinguished from the γ -form by the absence of twinning and the parallel extinction. H. le Chatelier found that calcium orthosilicate is readily decomposed by hot or cold, dil. or conc. soln. of ammonium salts. The action of acids is still more rapid. The decomposition by carbonic acid is much faster than is the case with the metasilicate. Hot or cold water has no appreciable action; and only a small proportion was dissolved after a month's action.

R. Kirwan,⁴ L. N. Vauquelin, and O. Bourgeois obtained glasses by fusing together mixtures of strontia and silica. G. Stein melted two mols of strontia and one mol of silica in a carbon tube and obtained only the metasilicate and carbide, but when a porcelain tube was employed, large, doubly-refracting, biaxial crystals of **strontium orthosilicate**, Sr_2SiO_4 , were obtained. The sp. gr. is 3.84 , and he gave for the m.p. 1593° . If cooled rapidly, a glass is produced. The diagram, Fig. 69, indicates the region of stability of strontium orthosilicate; its m.p. was found by P. Eskola to be above the range of the platinum resistance furnace. G. Stein gave 1593° for the m.p. No evidence of polymorphic forms was obtained by heating the crystals between 990° and 1634° ; by slow cooling; or by melting with strontium chloride. The salt did not show the phenomenon of dusting exhibited by the calcium salt. The indices of refraction with the F -ray, Ti -ray, D -ray, and the C -ray were respectively $\alpha = 1.740, 1.7325, 1.7275$, and 1.722 ; $\beta = 1.744, 1.737, 1.732$, and 1.727 ; and $\gamma = 1.766, 1.760, 1.756$, and 1.752 . The optic axial angle $2E = 58^\circ$, and $2V = 32^\circ 36'$. The optical character is positive. The twinning of many crystals on the (100)-plane was observed. The crystals are thought to be monoclinic or possibly rhombic. W. Pukall made some observations on strontium orthosilicate.

R. Kirwan, B. Kerl, and G. Wagener obtained glasses by fusing together mixtures of baryta and silica. C. L. Bloxam studied the expulsion of water from barium hydroxide by heating it with silica. A. Mitscherlich noted that much heat is evolved when silica is dissolved in baryta at a white heat. The crystalline product is readily soluble in hydrochloric acid. G. Stein, by the above-named process, obtained only the metasilicate. H. le Chatelier did not make **barium orthosilicate**, Ba_2SiO_4 , but obtained a sintered mass with a crystalline structure by heating the necessary components in a wind-furnace. The product when treated with water decomposed into barium hydroxide and the hydrated metasilicate. E. Jordis said that it is doubtful if the barium orthosilicate so produced is a homogeneous individual. W. Pukall made some observations on barium orthosilicate. The diagram, Fig. 70, indicates the region of stability of barium orthosilicate; and its m.p. was found by P. Eskola to be higher than that of platinum. F. M. Jäger and H. S. van Klooster said the m.p. exceeds 1750° . The crystals were found by P. Eskola to be in the form of rounded grains, and they did not show any cleavages or twinning. The indices of refraction for the D -ray were $\alpha = 1.810 \pm 0.005$, and $\gamma = 1.830 \pm 0.005$. Both H. le Chatelier and E. Jordis failed to prepare the orthosilicate by wet processes. F. Pisani reported $3\text{BaO} \cdot 2\text{SiO}_2 \cdot 2\text{H}_2\text{O}$, but he made a mistake in the calculation of his results; his product was probably the hexahydrated metasilicate (*q.v.*).

The anhydrous metasilicates.—The most important of the calcium silicates occurring in nature is **calcium metasilicate**, CaSiO_3 , known as the mineral **wollas-**

tonite. This name was applied in honour of W. H. Wollaston, and, according to C. C. von Leonhard,⁵ it was catalogued by S. L  man as a specimen found at Capo di Bove, near Rome, and it was supposed to be different from the ordinary tabular spar. In 1793, A. St  tz first described the mineral as *tabular spar*, and A. Estner used the same term in 1797. M. H. Klaproth analyzed it in 1802. D. L. G. Karsten called it *grammite*, and A. G. Werner, *Schalstein*. R. J. Ha  y first called it *spath en tables*, but later he called it **wollastonite**, a term used at the present day.

Wollastonite is rarely found in eruptive rocks, but is commonly found as a product of contact metamorphism, more particularly in granular limestones. It occurs in felspathic schists, basalts, etc.; and A. Lacroix found wollastonite associated with ap  lite. F. A. Waichner, F. Koch, and J. H. L. Vogt described the occurrence of the crystals in blast furnace slags, and in volcanic lavas. A.⁶ Gurit, F. Koch, F. Fouqu  , J. Morozewicz, etc., L. Appert and J. Henrivaux found wollastonite crystals in devitrifying glass. R. Br  n  s showed that the devitrification product is possibly a tetragonal modification, and he found it in the obsidian glass in a tunnel at Pisona. He proposed to call the natural tetragonal form *bourgeoisite*. C. V  lain reported wollastonite in the slag formed during the burning of some corn-stacks. G. vom Rath described its occurrence at Kaiserstuhl, and P. Platz, at Bellenwald in Baden; C. W. C. Fuchs, P. Platz, P. Groth, and A. Streng, at Auerbach in Hessen; P. Platz, at Pfaffenruth, and F. Sandberger, at Schweinheim and Gailbach in Bavaria; A. Frenzel, at Lengfeld and Berggiesh  bel in Saxony; E. Leisner, and E. Schuhmacher, at Geppersdorf, and H. Traube, at Neudeck in Silesia; F. Katzer, at Humpoletz in Bohemia; V. R. von Zepharovich, at Blunda in M  hren; K. F. Peters, F. Hessenberg, F. Sandberger, L. S. Szathm  ry, and V. R. von Zepharovich, at Rezbanya and Cziklova in Hungary; G. vom Rath, A. d'Achiardi, L. Busatti, G. Str  ver, A. des Cloizeaux, F. von Kobell, T. Monticelli and N. Covelli, A. Scacchi, B. Miersch, and P. Grosser, in Elba, Sardinia, Bracciano, Capo di Bovo, and Vesuvius in Italy; F. Fouqu  , K. von Seebach, F. Hessenberg, and A. Michel-L  vy and A. Lacroix, in Santorin, Greece; A. Piquet, and G. A. Kennigott, at Merida in Spain; A. Lacroix, and C. W. Cross, at Argent  ra and Roguedas in France; R. P. Greg and W. G. Lettsom, at Dunmore Head in Ireland, and near Aberdeen in Scotland; A. Erdmann, P. Groth, A. E. T  rnebohm, F. von Kobell, W. Hisinger, G. A. Kennigott, and G. Forchhammer, at G  kum, Wettersee, Aln  , etc., in Sweden; A. E. Nordenskj  ld, and F. J. Wuk, in Finland; A. des Cloizeaux, A. Lagorio, and N. von Kokscharoff, at Wilna, Kasbek, etc., in Russia; H. Wulf, O. M  gge, and G. G  rlich, in Damaraland, Namaqualand, and Massaland, Africa; L. H  ndeshagen, in Sumatra; A. K. Coomaraswamy, in Ceylon; T. Wada, in Japan; G. C. Hoffmann, at Grenville, North Burgess, etc., in Canada; and L. Vanuxem, H. Seybert, J. D. Whitney, J. D. Dana, E. A. Schneider, J. F. Williams, etc., in Bucks County, Willsborough Diana, Bonaparte Lake, etc., in the United States. The mineral *wilnite* (or *vilmite*) from Wilna (or Vilna) was shown by A. des Cloizeaux to be wollastonite. The calcium trisilicate, $2\text{CaO} \cdot 3\text{SiO}_2$, found at   delfors, and G  lleb  k (Norway), by W. Hisinger, and named *  delforsite*, was shown by G. Forchhammer to be wollastonite contaminated with quartz, felspar, garnet, and sometimes with calcium carbonate. Analyses have been made by C. F. Rammelsberg, R. Brandes, F.⁷   . Beudant, M. H. Klaproth, H. Traube, J. Loczka, F. Stromeyer, H. St. C. Deville, J. Lemberg, F. von Kobell, A. Funaro, G. vom Rath, A. von Reis, F. Fouqu  , A. Piquet, M. F. Heddle, C. E. Weidling, W. Hisinger, H. Rose, O. Widman, L. C. Beck, P. A. von Bonsdorff, N. von Kokscharoff, H. Wulf, L. Vanuxem, H. Seybert, J. D. Whitney, J. H. L. Vogt, W. Hampe, G. Tschermak, E. Manasse, A. d'Achiardi, F. Zambonini, C. Doelter, P. P. Sustchinsky, T. Wada, L. H  ndeshagen, A. K. Coomaraswamy, E. A. Schneider, J. F. Williams, L. S. Szathm  ry, etc. *Vide* laumontite.

F. Zambonini⁸ described a pale blue mineral from Vesuvius, found in loose nodules, which he called *rivaite*—after C. Riva. Its composition approximated $(\text{Ca}, \text{Na})_2\text{Si}_2\text{O}_6$. The sp. gr. was 2.55–2.56; and the hardness 5. The birefringence was weak. N. L. Bowen showed, however, that rivaite is heterogeneous, being wollastonite embedded in a blue glass. The same remark applies to the so-called *reasmurite*.

Calcium metasilicate exists in at least two forms—natural wollastonite, which is monoclinic, and artificial **pseudowollastonite**, which is pseudohexagonal. Both forms can be prepared artificially. The two forms are sometimes mistaken for one another, and although wollastonite has been frequently reported in slags and glasses—*vide supra*—J. H. L. Vogt,⁷ and P. Heberdey said that it is rarely found in slags, while pseudowollastonite is common. According to J. H. L. Vogt, the synthetic wollastonite prepared by B. Mauritz, and L. S. Szathm  ry was really pseudowollastonite. According to E. T. Allen and W. P. White, wollastonite is

stable only below 1190°, and above that temp. it passes into pseudowollastonite. By heating a glass of the composition CaSiO_3 between 800° and 1000°, crystals of wollastonite were formed. The conversion of pseudowollastonite to wollastonite was effected by dissolving the former in molten calcium vanadate and crystallizing between 800° and 900°. The fact that pseudowollastonite does not occur in nature is taken to show that rocks containing free calcium metasilicate must have crystallized at temp. below the inversion point of wollastonite. Pseudowollastonite has also been called α -wollastonite, and the ordinary form β -wollastonite; but since in other cases of allotropism, the α -form is the variety stable at a low temp., pseudowollastonite is designated β - CaSiO_3 , i.e. β -wollastonite, in Fig. 72, and wollastonite, α - CaSiO_3 , i.e. α -wollastonite.

N. G. Sefström obtained a vitreous mass mixed with acicular crystals by melting a mixture of equimolar proportions of quartz and marble. H. Lechartier melted a mixture of silica, lime, and calcium chloride and obtained what he regarded as crystals of wollastonite; and A. Gorgeu obtained similar crystals by heating a mixture of silica, and calcium oxide and chloride in a current of steam. J. H. L. Vogt, however, showed that the alleged wollastonite was probably the pseudo-variety. L. Bourgeois melted equimolar parts of lime and silica in a platinum crucible; the cooled mass was then slowly heated nearly to the m.p., and needle-like crystals appeared near the walls of the crucible. By heating the mass for two days, needle-like crystals 2-3 mm. long and 0.1 mm. thick were obtained. E. Hussak obtained wollastonite by fusing and slowly cooling a glass containing silica, lime, soda, and boric oxide—say, a mixture of sodium metasilicate and calcium borate. The crystals appear to be formed best in the presence of an *agent minéralisateur*—e.g. boric oxide (E. Hussak), sodium or calcium fluoride (C. Doelter, B. Karndöf, and F. Tursky), calcium chloride (H. Lechartier, and A. Gorgeu), and calcium vanadate (E. T. Allen and W. P. White). G. Oddo, H. le Chatelier, G. Tschermak, and G. Stein made crystals of pseudowollastonite from a molten mixture of lime and silica. The formation of pseudowollastonite in slags has also been discussed by F. Koch, C. Schnabel, J. F. L. Hausmann, L. Bourgeois, P. Heberdey, C. Doelter, J. H. L. Vogt, etc. G. V. Wilson observed the formation of crystals of wollastonite, but not pseudowollastonite, in glasses. W. Löwenstein noted the formation of calcium metasilicate when silica is dissolved in molten calcium chloride—*vide* silica. A. Daubrée claimed to have made wollastonite in microscopic needles by the action of superheated steam on a glass tube, but J. H. L. Vogt contested this statement. C. Doelter, however, heated a mixture of calcium carbonate and silicic acid in a sealed iron tube at 400°-425°. It was not possible to isolate the product from the excess of silica, but the monoclinic crystals closely resembled those of wollastonite. The genesis of wollastonite in nature has been discussed by U. Grubenmann, G. Spezia, V. M. Goldschmidt, C. Doelter, etc.

Wollastonite occurs in white, grey, yellow, or brown tabular crystals which are monoclinic prisms. P. Groth⁸ gives for the axial ratios $a : b : c = 1.0523 : 1 : 0.9694$, and $\beta = 95^\circ 24'$. Measurements of the crystals of native wollastonite were made by R. J. Haty, W. Phillips, F. Mohs, H. J. Brooke, F. von Kobell, J. F. L. Hausmann, A. des Cloizeaux, H. Rose, A. Michel-Lévy and A. Lacroix, G. vom Rath, C. F. Rammelsberg, A. Funaro and L. Buzatti, N. von Kokscharoff, F. Hessenberg, etc. Fig. 72 represents the crystals from Diana, measured by J. D. Dana, with c (001), a (100), v (101), t (101), and h (540). According to E. T. Allen and W. P. White, the lath-shaped crystals of artificial wollastonite often present the same arrangement of divergent fibres as is given by natural wollastonite, and the two kinds are similar in every respect. The crystals often show perfect cleavage cracks parallel to the long direction. The crystals of pseudowollastonite appear in the form of small irregular grains often tabular in shape; in short prisms; or else as fibres arranged in parallel or divergent groups. C. Doelter, and J. H. L. Vogt

FIG. 72.—Wollastonite from Diana.

consider the crystals of pseudowollastonite to be hexagonal. L. Bourgeois, A. L. Day and co-workers, and B. T. Allen and W. P. White have shown that the crystals are pseudo-hexagonal, and are probably monoclinic. The crystals often show distinct and repeated twinning lamellae parallel to the basal pinacoid and with an extinction angle of 2° . E. Kittl measured the rate of crystallization of wollastonite and found a curve, Fig. 73, with a sharp maximum at the most favourable temp. The maximum is about 20° below the temp. at which crystallization begins. He estimated that during crystallization there are 330 crystallization centres per sq. cm.

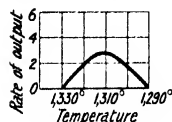

FIG. 73.—Effect of Temperature on the Speed of Crystallization.

H. Traube gave 2.81 for the sp. gr. of wollastonite; C. F. Peters, 2.919; A. Funaro and L. Buzatti, 2.7–2.8; and A. Piquet, 2.80. E. T. Allen and W. P. White found the sp. gr. of fibrous wollastonite made by the devitrification of glass to be 2.915 at $25^\circ/25^\circ$, and the sp. gr. of the glass, 2.904, at $25^\circ/25^\circ$; and the sp. gr. of the crystals from calcium vanadate, 2.913 at $25^\circ/25^\circ$; the sp. gr. of pseudowollastonite under similar conditions was 2.912, so that the differences observed might be attributed to experimental error. R. C. Wallace found the sp. gr. of pseudowollastonite to be 2.91 at 18° , and the mol. vol., 40. J. H. L. Vogt gave 2.86 for the sp. gr. of pseudowollastonite, and C. Doelter, 2.88–2.90. P. Lebedew found the sp. gr. of pseudowollastonite to be 2.88, and the hardness 3.5. The hardness of wollastonite is 4–5. The coeff. of thermal expansion of the glass calculated by A. Winklemann and O. Schott's rule⁹ is 0.000028. A. Brun gave 1366° for the m.p. of wollastonite crystals from Auerbach. O. Boudonard gave 1440° for the m.p. of the metasilicate, and O. Schott, 1300° (1450°); A. S. Ginsberg, and S. Smolensky, 1512° ; E. Rieke, 1525° ; H. Philippi, 1515° ; and N. V. Kultascheff, $>1400^\circ$. A. L. Fletcher, 1253° – 1258° ; and C. Doelter, 1240° – 1265° for the m.p. of the crystals, from Auerbach; 1245° – 1265° for those from Czikkowa; 1250° – 1300° for those from Diana; 1235° – 1275° for those from Elba; and 1260° – 1325° for those from Kimito—the first number represents the temp. at which fusion begins, the last number the temp. at which the silicate is fluid. E. T. Allen and W. P. White, A. L. Day and E. S. Shepherd, and J. P. Lebedew gave 1512° for the m.p. of pseudowollastonite; G. A. Rankin and F. E. Wright gave $1540^\circ \pm 2^\circ$. R. C. Wallace found the crystallization of the molten mass begins at 1502° . R. Lorenz and W. Herz studied the relation between the m.p. and the transition temp. H. Kopp gave 0.178 for the sp. ht. of wollastonite between 19° and 51° ; and W. P. White gave:

	100°	500°	700°	900°	1100°	1300°
Pseudowollastonite	—	0.2164	—	—	0.2377	0.2419
Wollastonite	0.1833	0.2174	0.2287	0.2354	0.2403	—

D. A. Tschernobajeff and S. P. Wologdine gave for the heat of formation, $(\text{CaO}, \text{SiO}_2) = 17.4$ Cals; and H. le Chatelier gave $\text{CaO} + \text{SiO}_2 = \text{CaSiO}_3 + 33.1$ Cals. The transition temp. of the enantiomorphic forms is given as 1180° by E. T. Allen and W. P. White, while G. A. Rankin and F. E. Wright gave 1200° , which is lowered to 1190° by the dissolution of 2 per cent. of calcium oxide, and raised to 1210° by the dissolution of 2 per cent. of silica.

E. Mallard¹⁰ found the indices of refraction of a sample of wollastonite from Pargas (Finland), to be $\alpha=1.619$, $\beta=1.632$, and $\gamma=1.634$; and A. Michel-Lévy and A. Lucroix, one from Czikkowa (Hungary), $\alpha=1.621$, $\beta=1.633$, and $\gamma=1.635$. For artificial or α -wollastonite, E. T. Allen and W. P. White, and G. A. Rankin and F. E. Wright found with sodium light $\alpha=1.616 \pm 0.002$, $\beta=1.629 \pm 0.002$, and $\gamma=1.631 \pm 0.002$; likewise for pseudowollastonite or β -wollastonite, $\alpha=1.610 \pm 0.002$, and $\gamma=1.654 \pm 0.002$. The birefringence of α -wollastonite is medium, $\gamma-\alpha=0.015$; that of β -wollastonite is strong, $\gamma-\alpha=0.041$; the extinction of α -wollastonite is parallel to the elongation. The optical character of α -wollastonite is negative, that of β -wollastonite positive. The optical axial angle of

α -wollastonite is about 70° ; and that of β -wollastonite is small being nearly uniaxial. A. des Cloizeaux found $70^\circ 40'$ for the optic axial angle of wollastonite with red light, 69° with green light, and $68^\circ 24'$ with violet light. He also found that an optic axial angle $73^\circ 32'$ at 17° became $73^\circ 4'$ at 126° . W. F. Hillebrand found some samples give a greenish-yellow thermoluminescence. K. Przibram studied the colour changes and the luminescence produced by radium rays. F. Farup and co-workers investigated the electrical conductivity of fused calcium silicates.

Wollastonite is soluble in hydrochloric acid, and gelatinous silica separates from the soln. The reaction was studied by G. Rose, and G. Tschernak. A. Gorgeu said that boiling hydrochloric acid completely decomposes the mineral; and with the dil. acid a part of the silica remains pulverulent and soluble in a soln. of sodium carbonate—the more conc. the acid the less residual silica. Cold dil. acetic acid does not appreciably affect the mineral. According to W. Flight,¹¹ a conc. soln. of sodium hydroxide attacks wollastonite, and lime and silica pass into soln. in the same proportions as they are present in the mineral. J. Lemberg found that when wollastonite is treated with a soln. of magnesium sulphate or chloride, wollastonite is transformed into a hydrated magnesium silicate. He also studied the exchange of bases with soln. of sodium and potassium silicates, and potassium aluminate. A. Gorgeu said that 0.01 grm. of wollastonite dissolves in about a litre of water. G. A. Kenngott observed that powdered wollastonite before and after calcination, reacts strongly alkaline to red litmus. A. Gorgeu found water sat. with carbon dioxide acts slowly on wollastonite; and C. Matignon and G. Marchal examined the corrosive action of water on wollastonite in the presence of carbon dioxide under ten atm. press. during 3 years. A. Gorgeu noted the solubility of wollastonite in fused calcium chloride from which it separates in fine crystals—*vide supra* in connection with the synthesis of wollastonite. According to G. E. Rankin and F. E. Wright, pseudowollastonite can take up 2 per cent. of lime or silica in solid soln. C. Doelter found that calcium metasilicate can dissolve 13 per cent. of silica. P. Lebedeff measured the f.p. of mixtures of calcium metasilicate and calcium sulphide. The corrosive action of the latter prevented experiments with mixtures containing over 50 per cent. of calcium sulphide. The curves are shown in Fig. 74. The solid soln. undergo a transformation at temp. below their f.p., the transformation curve having a maximum at about 1300° and 20 mol. per cent. of calcium sulphide. Rapidly cooled mixtures disintegrate completely when cold, whilst slowly cooled mixtures show, when examined microscopically, separate crystals of the pseudowollastonite and of calcium sulphide identical with the *oldhamite*, CaS , found by N. S. Maskeylyne, W. Flight, C. Friedheim, E. Cohen, G. Hinrichs, and J. van Laar in meteorites. W. S. Patterson and P. F. Summers found that alumina and magnesia decreased, while ferric oxide increased, the fluidity of fused calcium monosilicate; while zinc oxide at first increased and then decreased the fluidity. O. Schott, and C. Zulkowsky discussed the hydration of calcium metasilicate contained in portland cement. H. le Chatelier found that when mixed with water charged with carbon dioxide, and left in an atm. of carbon dioxide, calcium metasilicate sets to a hard mass; E. Landrin based on this fact an hypothesis on the setting of cements. On the other hand, when finely powdered and left for several days in water, in soln. of ammonium salts, or in lime-water, the silicate does not change, and this is taken to show that it cannot take part in the normal hardening of cements. W. Suida noted that wollastonite is feebly stained by basic aniline dyes. H. Hanemann said that molten cast iron reduces calcium metasilicate to silicon. N. G. Chatterji and N. R. Dhar found that calcium silicate is not peptized by a conc. soln. of cane sugar.

G. Stein¹² prepared **strontium metasilicate**, SrSiO_3 , by melting equimolar

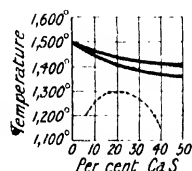

FIG. 74. —Freezing Curves of Mixtures of Calcium Metasilicate and Sulphide.

parts of strontia and silica in a carbon tube. When quickly cooled, doubly refracting granules are obtained; and with slow cooling prismatic crystals are formed. The glass was not produced—*vide* the orthosilicate. P. Eskola found the zone of stability of strontium metasilicate indicated in Fig. 69. Attempts were made to prepare polymorphic forms analogous with those of the calcium salt by holding the glass at 1020° ; by melting with strontium chloride, and with strontium vanadate, but without success. F. M. Jäger and H. S. van Klooster also obtained only one form with sodium tungstate as a flux. Strontium metasilicate furnishes one form which closely resembles pseudowollastonite, or β - CaSiO_3 . The crystals are pseudohexagonal, uniaxial and positive, and the characteristic habit is tabular parallel to (0001)-face. On account of the resemblance to an isomorphism with β - CaSiO_3 , the crystals might be supposed monoclinic, but decisive evidence was not obtained by P. Eskola, who found the axial ratio for the presumably pseudohexagonal crystals to be $a:c=1:0.98$. There is a fairly good basal cleavage. The pyramidal faces of the crystals are striated parallel to the edge with the basal plane; and most of the crystals are twinned on the base. G. Stein found the sp. gr. of the slowly cooled salt to be 3.90, and if rapidly cooled, 3.89; F. M. Jäger and H. S. van Klooster gave 3.652 at $25.1^{\circ}/4^{\circ}$; and P. Eskola, 3.650 at $30^{\circ}/4^{\circ}$, and 3.653 at $25^{\circ}/4^{\circ}$. G. Stein gave 1287° for the m.p.; R. C. Wallace, 1529° ; F. M. Jäger and H. S. van Klooster, $1578^{\circ} \pm 1^{\circ}$; and P. Eskola, $1580^{\circ} \pm 4^{\circ}$. The indices of refraction of granular crystals for the F -, TL -, D -, and C -rays are respectively $\alpha=1.606$, 1.602 , 1.599 , and 1.596 ; and $\beta=1.646$, 1.641 , 1.637 , and 1.634 . F. M. Jäger and H. S. van Klooster gave $\alpha=1.590$ and $\beta=1.620$. W. Pukall made some observations on this silicate.

O. Bourgeois made a crystalline mass of **barium metasilicate**, BaSiO_3 , by reheating the product obtained by melting the two constituents. G. Stein made crystals of the compound by a process similar to that which he employed for strontium metasilicate—*vide* barium orthosilicate. P. Eskola found the zone of stability of barium metasilicate indicated in Fig. 70. Crystals were obtained in the form of rounded globules or short rods with rounded ends having a negative elongation and parallel extinction. The crystals were monoclinic, and no evidence of polymorphic forms was obtained by heating at 1100° , or by fusion with barium vanadate, and F. M. Jäger and H. S. van Klooster obtained only one form by fusion with sodium tungstate. There is a well-developed cleavage parallel to $a\beta$, and sometimes blue interference colours are obtained. The optic axial angles are $2E=50^{\circ}$, and $2V=29^{\circ}$. G. Stein found the sp. gr. of the crystals is 3.77, and of the glass 3.74; F. M. Jäger and H. S. van Klooster gave 4.435 at $25^{\circ}/4^{\circ}$; R. C. Wallace gave 4.44 for the sp. gr. at 18° ; and P. Eskola, 4.399 at 4° . R. C. Wallace gave 1490° for the m.p.; G. Stein gave 1368.5° ; P. Lebedeff, 1438° ; S. Smolensky, 1470° ; F. M. Jäger and H. S. van Klooster, $1604^{\circ} \pm 0.5^{\circ}$; and P. Eskola, 1604° . The m.p. of the metasilicates of the three alkaline earths increases regularly with increasing at. wt. of the metal. P. Eskola found the indices of refraction for the F -, TL -, D -, and C -rays were respectively $\alpha=1.682$, 1.677 , 1.673 , and 1.669 ; $\beta=1.684$, 1.678 , 1.674 , and 1.670 ; and $\gamma=1.688$, 1.682 , 1.678 , and 1.673 . The birefringence is very weak. F. M. Jäger and H. S. van Klooster gave $\alpha=1.670$ and $\gamma=1.667$. E. Jordis, and W. Pukall made some observations on this silicate.

The hydrated calcium silicates.—F. E. Wright¹³ found rhombic, white, or pale green crystals of a radiating fibrous mineral in the Velardena district, Mexico, which he named **hillebrandite**—after W. F. Hillebrand. According to E. T. Allen's analysis, the composition corresponds with **monohydrated calcium orthosilicate**, $\text{Ca}_2\text{SiO}_4 \cdot \text{H}_2\text{O}$. The mineral occurs in radial fibres possibly rhombic. The sp. gr. is 2.692 at 25° ; the hardness 5–6; the indices of refraction $\alpha=1.605$, $\beta=1.612$, and $\gamma=1.612$. The optic axial angle is 60° – 80° ; and the crystals are optically negative. Water decomposes the mineral; it is attacked by hydrochloric acid; and fuses to a white enamel before the blowpipe. F. W. Clarke suggested that this mineral may really be **calcium dihydroxymetasilicate**, $(\text{CaOH})_2\text{SiO}_3$. B. von

Ammon treated a dil. aq. soln. of calcium chloride with an excess of crystallized sodium silicate, and obtained a gelatinous precipitate which was partially decomposed by atm. carbon dioxide. The composition corresponded with a *hydrated calcium metasilicate*. W. Pukall similarly obtained a product with the composition, $\text{CaSiO}_3 \cdot 2\frac{1}{2}\text{H}_2\text{O}$. As previously indicated, the calcium silicates prepared in the wet way can be regarded only as arbitrarily selected stages in the progressive hydrolysis of the hydrated silicate, and almost pure silica can be obtained if the washing be prolonged. The washing of the alkali from B. von Ammon's product must therefore be a serious disadvantage. E. Jordis and E. H. Kanter claim to have made **monohydrated calcium metasilicate**, $\text{CaSiO}_3 \cdot \text{H}_2\text{O}$, by boiling hydrated silica containing at least 23 per cent. of water, or a 1.8 per cent. sol of silicic acid, and lime-water. The product is indistinctly crystalline. A. Gages said that the monohydrate remains as a residue when the dihydrated disilicate, $(\text{CaSiO}_3)_2 \cdot 2\text{H}_2\text{O}$, is treated with a soln. of potassium hydroxide. A. S. Eakle reported a snow-white earthy mineral, the **hemitrihydrated calcium metasilicate**, $\text{CaSiO}_3 \cdot \frac{3}{2}\text{H}_2\text{O}$, in the limestone of Crestmore, Cal., and he called the mineral **crestmoreite**. It may be an orthosilicate, $\text{H}_2\text{CaSiO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$. The extinction is straight; the elongation, positive; the birefringence, low; the index of refraction, 1.590, or $\alpha = 1.593$, $\beta = 1.603$, and $\gamma = 1.607$. The sp. gr. is 2.22, and the hardness, 3. Crestmoreite is readily decomposed by acids with the separation of some of the silica as hydrogel; and boiling water extracts some calcium. At 200° , 3.27 per cent. of water is evolved, and at 300° , 10.27 per cent. A. S. Eakle found a white fibrous **hemihydrated calcium metasilicate**, $(\text{CaSiO}_3)_2 \cdot \frac{1}{2}\text{H}_2\text{O}$, in the massive idocrase, at Crestmore, Cal., and he called it **riversideite**. The extinction is straight; the elongation, positive; the refractive indices, $\alpha = 1.595$, $\beta = 1.60$, and $\gamma = 1.603$; the sp. gr. 2.64, and the hardness, 3. It is soluble in hydrochloric acid.

J. Parry and F. E. Wright assigned to a colourless mineral from the Dutoitspan Mine, Kimberley, the name **afwillite**—after A. F. Williams, who discovered it in the mine. The analyses agree closely with $3\text{CaO} \cdot 2\text{SiO}_2 \cdot 3\text{H}_2\text{O}$, and since only a small proportion of the water is evolved below 300° , and all is expelled at about 900° , the water is considered to be an integral part of the mineral, and not zeolitic. They consider it to be a basic orthosilicate, $2\text{H}_2\text{CaSiO}_4 \cdot \text{Ca}(\text{OH})_2$; but it may also be represented as **trihydrated calcium orthosilicate**, $(\text{Ca}_3\text{Si}_2\text{O}_7) \cdot 3\text{H}_2\text{O}$. The monoclinic prismatic crystals have the axial ratios $a:b:c = 2.097:1:2.381$, and $\beta = 98^\circ 26'$. The corrosion figures with hydrochloric acid on the (001)-face agree with the monoclinic symmetry; the cleavage parallel to the (001)-face is perfect, and that parallel to the (100)-face is noticeable. The sp. gr. is 2.630 at 18° ; and the hardness, 4. The optic axial angle $2E = 94^\circ 08'$ for the Li-line, $96^\circ 05'$ for the Na-line; and $96^\circ 18'$, $97^\circ 13'$, and $100^\circ 28'$ for the mercury lines of the respective wave-lengths 578μ , 546μ , and 536μ ; while $2V = 54^\circ 40'$ for the Na-line, and $55^\circ 00'$ for the line of wave-length 546μ . The optical character is positive. The refractive indices α , β , and γ are respectively 1.6148, 1.6179, and 1.6312 for the helium red line (668μ); 1.6169, 1.6204, and 1.6336 for the Na-line (589μ); and 1.6201, 1.6236, and 1.6366 for the mercury green line (546μ). Water has a slow action on the mineral, and the liquid colours red-litmus blue; and phenolphthalein, red. Both sulphuric and hydrochloric acids attack the mineral freely.

E. Jordis obtained **dihydrated calcium metasilicate**, $\text{CaSiO}_3 \cdot 2\text{H}_2\text{O}$, contaminated with 3 per cent. of acetic acid, by adding hydrated silica to a soln. of calcium acetate sat. with calcium hydroxide; when repeatedly washed with a soln. of potassium hydroxide, the acetic acid is removed, and the monohydrate remains. Some observations on this hydrate were made by W. Heldt, E. Tischler, and others—*vide supra*. H. le Chatelier prepared a hydrated silicate by adding an excess of lime-water to a colloidal soln. of silicic acid. The precipitate is very voluminous, for after complete deposition a gram occupies 2 litres. A certain amount of this was suspended in almost sat. lime-water, and after settling, half the liquor was removed, analyzed, and replaced by water. The operation was repeated a number of times,

and if *a* grms. represents the total amount of lime removed; and *b* grms. the quantity of lime in soln. per litre of liquor :

<i>a</i>	0.000	0.500	0.755	0.890	0.955	0.990	1.030	1.070
<i>b</i>	1.000	0.510	0.270	0.140	0.085	0.065	0.053	0.052

Hence, the conc. of the soln. at first decreased very nearly proportionally with the vol. of water added, showing that the quantity of lime given to the liquid by the precipitate is nearly zero; but when the quantity of lime in the liquor has fallen to 0.052 grm. per litre, the addition of fresh water no longer changes the lime content of the liquor. This shows that in accord with the law of mass action, the hydrolysis of the silicate introduces lime to the liquid. After standing 6 months, in contact with a sat. soln. of lime-water, the composition of the precipitate approximates $1.7\text{CaO} \cdot \text{SiO}_2 \cdot \text{Aq.}$, although at the moment of precipitation the composition was $1.3\text{CaO} \cdot \text{SiO}_2 \cdot \text{Aq.}$ By washing the precipitate until the filtrate contains a little more than 0.052 grm. of lime per litre, at which conc. the decomposition of the silicate begins, the product contains $1.1\text{CaO} \cdot \text{SiO}_2 \cdot \text{Aq.}$ The excess of lime is taken to be adsorbed calcium hydroxide; and, allowing for this, the analysis corresponds with **hemipentahydrated calcium metasilicate**, $\text{CaSiO}_3 \cdot 2\frac{1}{2}\text{H}_2\text{O}$.

A. Daubr e reported the occurrence of dihydrated calcium metasilicate, $\text{CaSiO}_3 \cdot 2\text{H}_2\text{O}$, which he called *plomb rite*, as a gelatinous suspension in the waters of the thermal springs at Plombi res. It dries to a hard mass on exposure to air. There is some doubt if this is an accurate interpretation of the facts. F. W. Clarke, regarding Si_2O_7 as a sexivalent radicle, represents plomb rite by the formula $(\text{a}(\text{Si}_2\text{O}_7)) : (\text{Ca} \cdot \text{Si}_2\text{O}_7 \cdot (\text{CaH})_2 + 9\text{H}_2\text{O})$. F. Cornu considers it to be a hydrogel, possibly of wollastonite.

C. Doelter said that wollastonite is formed when the hydrated metasilicate is calcined between 300° and 1100° . B. von Ammon found that the fresh precipitate dissolves in water—perhaps as a peptized colloid. It is decomposed by hydrochloric acid before or after calcination; and if it has been strongly calcined, the separated silica is granular. The precipitate is also decomposed by carbon dioxide.

In 1866, C. F. Rammelsberg¹⁴ described a mineral which he named **xonotlite** because it was obtained from Tetela de Xonotla (Mexico). A similar mineral was obtained by M. F. Heddle from Loch Scarpden, Isle of Mull (Scotland). C. F. Rammelsberg's analyses agree with **pentitahydrated calcium metasilicate**, $\text{CaSiO}_3 \cdot \frac{5}{2}\text{H}_2\text{O}$, and he regards the mineral as a transformation product of wollastonite. A. Lacroix, and P. Groth emphasized the optical and structural resemblance of xonotlite to okenite (*vide infra*). The sp. gr. is 2.710–2.718; that of M. F. Heddle's sample was 2.05; and the hardness, $6\frac{1}{2}$. E. V. Shannon found the mineral at Leesburg, Virginia, is biaxial and positive, with the indices of refraction $\alpha=1.583$, $\beta=1.583$, and $\gamma=1.595$. Hydrochloric acid decomposes the mineral with the separation of gelatinous silica. The *calcite* described by E. S. Larsen was later shown to be identical with xonotlite. G. M. Schwartz found xonotlite nodules surrounded by a border of diopside. The so-called *natroxonotlite* found by J. F. Williams in the sulphur springs at Magnet Cove, Arkansas, is considered to be a transformation product of wollastonite. The analysis approximates to $\text{RSiO}_3 \cdot \frac{5}{2}\text{H}_2\text{O}$, where R represents 0.9Ca and 0.1Na.

J. Dalton,¹⁵ F. Kuhlmann, and B. von Ammon obtained hydrated silicates by the action of strontia or strontium salts on a soln. of water-glass. E. Jordis and E. H. Kanter made **monohydrated strontium metasilicate**, $\text{SrSiO}_3 \cdot \text{H}_2\text{O}$, by boiling dialyzed silicic acid with strontium hydroxide, or by the action of silica hydrogel, with at least 23 per cent. of water, on a soln. of strontium hydroxide. It is more stable than the calcium salt and less stable than the barium salt. The white crystalline powder is decomposed by boiling with water, forming an acid silicate; and an acid silicate is produced by mixing strontium hydroxide with silica hydrogel containing less water than has just been indicated. E. W. Prevost, W. Wahl, E. Jordis, and B. von Ammon obtained hydrated products by the action of baryta or of barium salts on a soln. of water-glass. The alkali requires a prolonged washing for its removal. E. Jordis and E. H. Kanter prepared **monohydrated barium metasilicate**,

$\text{BaSiO}_3\text{H}_2\text{O}$, as a white crystalline powder, by a process similar to that employed for the strontium salt.

According to H. le Chatelier, when a soln. of sodium silicate or colloidal silicic acid is treated with baryta-water, a voluminous precipitate is formed. It appears to be amorphous, but is probably crystalline when the crystals are too small to be visible under high magnification. If allowed to stand 24 hrs., the precipitate collects as a thin layer of tabular crystals visible to the naked eye. Comparatively large crystals can be obtained by allowing superposed soln. of sodium silicate and barium hydroxide to mix slowly by diffusion. A prolonged washing decomposes the crystals. At 15° , the decomposition stops when the washing liquor has 0.91 gm. of baryta per litre. The analysis agrees with **hexahydrated barium metasilicate**, $\text{BaSiO}_3 \cdot 6\text{H}_2\text{O}$. Rather more water was found in some analyses, probably owing to the presence of water occluded by the crystals. H. Bäckström's analyses corresponded with $5\text{H}_2\text{O}$; W. Wahl's and J. M. van Bemmelen's with $6\text{H}_2\text{O}$. According to F. Pisani, and H. le Chatelier, the same crystals are produced spontaneously in laboratory bottles of baryta-water at the expense of the silica of the glass. The crystals collect on the sides of the bottle. F. Pisani's formula is wrong owing to an error in his calculation. J. M. van Bemmelen found that a small quantity of baryta converts the hydrosol into the hydrogel, by which baryta is also absorbed. When mol. proportions of silicon dioxide and barium hydroxide are taken, the crystalline hexahydrate separates. E. Jordis found that a homogeneous product is not formed by the action of quartz or silica hydrate on baryta-water. A. Cossa and G. la Valle found that one mol. of the water of crystallization is retained more tenaciously than the remaining five, and, according to W. Wahl, the formula may be $\text{BaH}_2\text{SiO}_4 \cdot 5\text{H}_2\text{O}$, analogous with diopase, $(\text{CaH}_2\text{SiO}_4)_n$. The dehydrated product can reabsorb some water. The crystals were found by J. M. van Bemmelen to be rhombic bipyramids with axial ratios, according to H. le Chatelier, of $a:b:c$ 1.1723:1:0.6628. The double refraction is weak. The heat of formation from dissolved baryta and gelatinous silica is 4 cal. The salt is decomposed by water; J. M. van Bemmelen said that 100 parts of water at 15° dissolve 0.17 part of the hexahydrate. Washing with hot water removes virtually all the barium. The salt is decomposed by carbon dioxide.

The mineral **okenite**, discovered by A. Breithaupt,¹⁶ was considered by C. F. Rammelsberg to be **dihydrated calcium metasilicate**, $\text{CaSi}_2\text{O}_6 \cdot 2\text{H}_2\text{O}$. It may be **monohydrated calcium metasilicate**, $\text{CaSi}_2\text{O}_6 \cdot \text{H}_2\text{O}$. C. Doelter regarded it as a solid soln. of calcium metasilicate and silicic acid, $\text{CaSi}_2\text{O}_6 \cdot \text{SiO}(\text{OH})_2 \cdot n\text{H}_2\text{O}$. Analyses of okenite were reported by F. von Kobell, J. Lemberg, A. Connell, P. A. Dufrenoy, E. E. Schmid, S. Meunier, T. L. Walker, J. T. Würth, C. von Hauer, O. B. Bögild, S. Haughton, L. Darapsky, etc. It occurs on the island of Disko in Greenland; at Poonah in India; near Rio Putagan in Chili, etc. A sample from Farøe Islands was called *dysclasite*—δύς, difficult; κλάω, to break—by A. Connell; and one from Bordoe, Farøe Islands, was called *bordite* by P. A. Dufrenoy. C. Doelter obtained it by heating in a sealed tube to about 200° , a mixture of calcium oxide or silicate, silicic acid, and carbonic acid. A. de Schulten obtained a product, which he likened to okenite, by heating the precipitate obtained by adding lime-water to a conc. soln. of potassium silicate in a glass tube at 180° – 220° for 24 hrs. The analysis, however, showed too little calcium oxide, too much silica, and 5.5 per cent. of alkalis derived in part from the glass containing vessel. E. Jordis also described the synthesis of amorphous okenite. W. Pukall obtained a similar product, $\text{CaSi}_2\text{O}_6 \cdot 24\text{H}_2\text{O}$, by the action of calcium chloride on a soln. of potassium disilicate. A. S. Eakle and A. F. Rogers described the alteration of wükeite to okenite. F. W. Clarke represented the formula of okenite:

The mineral occurs as a white fibrous or compact aggregate of needle-like crystals belonging, said A. Breithaupt, to the rhombic system. O. B. Böggild assigned the mineral to the triclinic system, and gave for the axial angles $\alpha=122^\circ 54'$, $\beta=67^\circ 46'$, and $\gamma=50^\circ 10'$; and 2.326-2.332 for sp. gr. of the crystals, and 2.325-2.323 for the sp. gr. of the aggregates. A. Breithaupt gave 2.5 for the sp. gr.; A. Connell, 2.362; P. A. Dufrénoy, 2.33; and E. E. Schmid, 2.324. S. Meunier found the sp. gr. to be 1.75 when the mineral was dried at 110° . A. Breithaupt gave 4-5 for the degree of hardness. C. Doelter said that when melted and slowly cooled pseudowollastonite is obtained, hence his hypothesis for the constitution of okenite; E. E. Schmid that okenite lost 2 per cent. of water when confined over conc. sulphuric acid; and on heating the mineral, 2.55 per cent. was lost at 100° ; 12.95 per cent. was lost when the mineral sintered; and 13.97 per cent. when the mineral fused. G. Tammann measured the vap. press. of okenite in equilibrium with atm. containing water vap. at the vap. press. p mm.; the vap. press. of the mineral changes continuously. Thus, at 19° :

Water	0.06	0.84	1.02	1.29	1.67	2.10	2.66	3.21	3.56 per cent.
p	15.72	14.55	12.48	9.11	6.05	1.23	0.39	0.11	—

As a rule, if definite hydrates are formed there are abrupt changes in the continuity of the curve; usually also hydration and dehydration are reversible; here, if the vap. press. falls below 1 mm., the rehydration does not reach its original value. O. B. Böggild classed okenite as a fibrous zeolite. A. Michel Lévy and A. Lacroix gave for the index of refraction, 1.556; and for the positive birefringence, $\gamma-\alpha=0.0091$. O. B. Böggild gave $\alpha=1.530$, and $\gamma=1.541$, for the indices of refraction, and he found the extinction with single crystals is parallel, and with aggregates, it is oblique up to 34° . The values $\alpha=1.512$, $\beta=1.514$, and $\gamma=1.515$ have been reported. The optic axial angle is large; and the optical character negative. When okenite is heated, water is given off, and the mineral becomes opaque; it finally melts with frothing to an opaque enamel. Hydrochloric acid decomposes the mineral with the separation of gelatinous silica. J. Lemberg studied the replacement of the calcium oxide in okenite by the action of a 10 per cent. soln. of potassium or sodium hydroxide, and by a soln. of sodium silicate at 100° . Between 9 and 10 per cent. of sodium oxide was introduced, and a little potassium oxide. Most of the calcium was replaced by magnesium when the okenite was digested for 15 days at 100° with a soln. of magnesium chloride.

There are a number of other ill-defined hydrated calcium silicates which occur as minerals. The mean of the number of analyses indicated in brackets is given in Table XV. They contain alkalis, magnesia, alumina, and iron oxides in quantities small enough to represent impurities. H. How¹¹ reported the occurrence of thin white plates of what he called *centrallassite* in the trap-rock of Bay of Fundy, Nova Scotia. W. F. Foshag represented it by the formula $4\text{CaO} \cdot 7\text{SiO}_2 \cdot 5\text{H}_2\text{O}$; and H. How, $2\text{CaO} \cdot 3\text{SiO}_2 \cdot 2\text{H}_2\text{O}$. The sp. gr. is 2.45-2.46; W. F. Foshag gave 2.51; hardness 2½-4; and indices of refraction, $\alpha=1.535$, $\beta=1.548$, and $\gamma=1.549$. With hydrochloric acid no gelatinous silica is formed. The mineral called *cyanolite* was found in the same locality. The amygdaloid nodules contained an inner bluish mass of cyanolite, a thin outer layer which H. How named *cerinite*, and an intermediate layer of *centrallassite*. Cyanolite forms a bluish-white amorphous mass of sp. gr. 2.495, which J. D. Dana suggested is a mixture of chalcedony and *centrallassite*. M. F. Heddle reported a compact, fine-grained, reddish-white mineral which he found near Tobermory, Isle of Mull, and which he called *tobermorite*. Its sp. gr. is 2.423. M. F. Heddle represented its composition by $3(4\text{CaO} \cdot \text{H}_2\text{O}) \cdot 5\text{SiO}_2 \cdot 10\text{H}_2\text{O}$; and P. Groth, by $\text{H}_2\text{Ca}_4(\text{SiO}_3)_3 \cdot 3\text{H}_2\text{O}$. G. vom Rath found white hexagonal crystals of a mineral which he called *chalcocorphite* in the lava of Nieder-Mendig. The axial ratio was $a:c=1:1.90914$; the sp. gr. 2.51-2.57; and the hardness 5. When treated with hydrochloric acid, it forms gelatinous silica.

T. Anderson found concretions of a radiating lamellar structure near Portree, Isle of Skye, and he called the mineral *guroilite*— $\gamma\mu\rho\acute{\iota}\tau\epsilon$, round; and *Albos*, a stone—W. H. Miller called it *gyrolite*. H. How also reported specimens from Port George, Nova Scotia; F. W. Clarke, and W. T. Schaller, from New Almaden and Fort Point, California; E. Hussak, from Mogy Guassa, Brazil; F. Cornu, from Poonah, India; F. N. A. Fleischmann, from Legoniel, Collinard, and Ballyhenry in County Antrim; etc. Other observations were made by R. P. Greg and W. G. Lettsom, M. F. Heddle, A. Lacroix, G. A. Kenngott, and

L. Saemann. Analyses were also made by these observers. They are summarized by the formula $2\text{CaO} \cdot 3\text{SiO}_2 \cdot 3\text{H}_2\text{O}$, or $2\text{CaO} \cdot 3\text{SiO}_2 \cdot 2\text{H}_2\text{O}$, corresponding with *dihydrated calcium mesotrisilicate*, $\text{Ca}_2\text{Si}_3\text{O}_8 \cdot 2\text{H}_2\text{O}$; or *calcium tetrahydrometatrissilicate*, $\text{Ca}_2\text{H}_2\text{Si}_4\text{O}_{12}$. F. Cornu gave the formula $4\text{CaO} \cdot 5(\text{H}, \text{K}, \text{Na})_2\text{O} \cdot 6\text{SiO}_2$; E. S. Dana, *calcium dihydro-trimetrasilicate*, $\text{H}_2\text{Ca}_2(\text{SiO}_3)_3 \cdot \text{H}_2\text{O}$; and F. W. Clarke, $\text{H}_2(\text{Si}_2\text{O}_7)(\text{Ca}(\text{Si}_3\text{O}_7)(\text{CaH}_2)_2)$. E. Baur obtained a silicate analogous to gyrolite by heating in an autoclave at 450° , mixtures of water-glass, potassium or sodium aluminate, calcium carbonate, potassium hydrocarbonate, and silica. F. Cornu's experiments in this direction were not successful. According to O. B. Bøggild, the crystals of the gyrolite belong to the trigonal system, and have the axial ratio $a:b=1:1.9360$. F. Cornu found the sp. gr. of samples from Bohemia to range from 2.343–2.368; from Greenland, from 2.388–2.422; and one from Brazil, 2.420. O. B. Bøggild found the sp. gr. of samples from Greenland ranged from 2.383–2.446. The hardness is between 3 and 4. The mineral is colourless or white. It is optically uniaxial or feebly biaxial. The cleavage is well marked. When heated, it fuses with swelling and forms a white glass. F. Cornu found the index of refraction of a number of samples, the ordinary ray to be between 1.445 and 1.548, and E. Baur gave $\omega=1.529$, $\epsilon=1.523$; so that the double refraction is $\omega-\epsilon=0.006$. J. Königsberger and W. J. Müller also measured the indices of refraction; and they found that the mineral has a higher refractive index and a feebler birefringence after it has been dehydrated. F. Cornu said gyrolite is readily soluble in dil. hydrochloric, nitric, or sulphuric acid; and that it gives a well-marked alkaline reaction when moistened with water. F. Cornu separated from gyrolite from Njakomat, Greenland, another mineral which was called *reyerite*. The composition is indicated in Table XV. The crystal form, hardness, solu-

TABLE XV.—ANALYSES OF SOME NATURAL HYDRATED CALCIUM SILICATES.

	K ₂ O	Na ₂ O	CaO	MgO	Al ₂ O ₃	FeO	Fe ₂ O ₃	SiO ₂	H ₂ O

bility, and behaviour when heated resemble those of gyrolite. The sp. gr. was found by F. Cornu to be 2.499–2.578, and by O. B. Bøggild, 2.578—values rather higher than those for gyrolite. F. Cornu's value for the index of refraction is $\omega=1.564$; and O. B. Bøggild gave $\omega=1.5645$, $\epsilon=1.5599$ —which are rather higher than for gyrolite. Reyevite is uniaxial, and optically positive. A. Pelikan¹⁸ referred to a mineral occurring at Gross-Priesen, Bohemia, etc., which he called *zephyllite*. It furnishes white or colourless crystals with the composition SiO_2 , 37.67 per cent.; CaO , 46.82; H_2O , 7.52; and F, 7.99. The crystals are rhombohedral with the basal cleavage perfect. F. Cornu studied the corrosion figures. A. Himmelbauer gave $\omega=1.565$ for the refractive index; and F. Cornu, 1.545. The optic axial angle is $2\epsilon=27\frac{1}{2}^\circ$. The sp. gr. is 2.764, and the hardness 3. A. S. Eskola described a mineral from Crestmore, California, which he called *foshagite*—after W. F. Foshag. Its composition corresponds with *calcium dihydrotriorthosilicate*, $\text{H}_2\text{Ca}_2(\text{SiO}_4)_3$; its sp. gr. is 2.36; its indices of refraction $\alpha=\beta=1.594$, and $\gamma=1.598$; and it is optically positive.

P. Eskola¹⁹ found the *barium mesodisilicate*, $\text{BaO} \cdot 2\text{SiO}_2$, or BaSi_2O_6 , is formed within the zone indicated in Fig. 69. The crystals were reported by N. L. Bowen to occur in baryta crown glass. The glass, $\text{BaO} \cdot 2\text{SiO}_2$, kept at 1385° , gave rhombic crystals of tabular habit parallel to $a\beta$. The cleavages are well marked in all the pinacoidal directions. The optic axial angle $2V=74^\circ 45'$; the sp. gr. was 3.73; the m.p. $1420^\circ \pm 4^\circ$; and the indices of refraction for the *D*-line are $\alpha=1.597$, $\beta=1.612$, and $\gamma=1.621$. The small differences in the properties of the mesodisilicate prepared from its constituents from that formed in baryta-crown-glass are possibly due to the latter holding a little alkali disilicate in solid soln. There was

no evidence of barium mesodisilicate holding alkali silicate in solid soln.; but it forms a well-defined series of solid soln., with the **barium mesotrisilicate**, $\text{Ba}_2\text{Si}_3\text{O}_8$, which was formed in granular rounded masses. The rhombic crystals are perfectly isomorphous with those of the mesodisilicate with which it forms a complete series of solid soln. It is unusual to find two compounds of the same element, so different in constitution, furnishing so complete and perfect an isomorphous series. The twinning is well marked. The cleavage is perfect along $\beta\gamma$, and poor along $\alpha\beta$, and $\alpha\gamma$. The optic axial angle $2V=53^\circ 30'$ to 58° . The sp. gr. is 3.93; the m.p. 1450° ; the indices of refraction for the D -line are $\alpha=1.620$, $\beta=1.625$, and $\gamma=1.645$. The optical character is positive. P. Eskola found no evidence of the corresponding strontium compounds. G. A. Rankin and co-workers prepared **calcium orthodisilicate**, $\text{Ca}_3\text{Si}_2\text{O}_7$, in colourless crystals belonging to the rhombic system—*vide* Figs. 71, and 60. The crystals are best obtained by holding the glass with 54.5–55.5 per cent. of lime at a temp. slightly lower than 1475° . G. V. Wilson obtained these crystals in the actions of glass on limestone. Calcium orthodisilicate exhibits an incongruent m.p. at $1475^\circ \pm 5^\circ$. The refractive indices are $\alpha=1.641$, and $\gamma=1.650 \pm 0.002$ for Na-light. The birefringence is weak, $\gamma-\alpha$ being about 0.01; the optic axial angle is large, and the optical character positive.

According to E. Martin,²⁰ when the silicic acid, $5\text{SiO}_2 \cdot 2\text{H}_2\text{O}$, derived from silicic acetate is treated with lime-water, *tetrahydrated calcium tetreropentasilicate*, $\text{Ca}_2\text{Si}_5\text{O}_{12} \cdot 4\text{H}_2\text{O}$, is formed; and if the silicic acid, $5\text{SiO}_2 \cdot \text{H}_2\text{O}$, derived from calcium silicate is similarly treated, *trihydrated calcium tetreropentasilicate*, $\text{Ca}_2\text{Si}_5\text{O}_{12} \cdot 3\text{H}_2\text{O}$, is formed. When this silicate is ignited, **calcium tetreropentasilicate**, $\text{Ca}_2\text{Si}_5\text{O}_{12}$, is produced. For E. Martin's pentasilicates $10\text{CaO} \cdot 5\text{SiO}_2$, *i.e.* $(\text{Ca}_2\text{SiO}_4)_5$; $(\text{Ca}_2\text{SiO}_4)_6 \cdot 2\text{H}_2\text{O}$; and $13\text{CaO} \cdot 5\text{SiO}_2$, *vide* cements.

H. le Chatelier²¹ melted a molar mixture of one of silica, two of calcium oxide, and four of calcium chloride at a dark red heat, and extracted the excess of calcium chloride by dried alcohol. Analyses correspond with **calcium chlororthosilicate**, $\text{Ca}_2\text{SiO}_4 \cdot \text{CaCl}_2$. A. Gorgeu obtained the same substance by fusing a mixture of silica and calcium chloride in the presence of water vap. E. Jordis and E. H. Kanter studied the reaction between calcium chloride lime-water and silica. The microscopic crystals of calcium chlororthosilicate belong to the rhombic system; they have the axial ratios $a : b : c = 0.726 : 10 : 287$. They exhibit a strong double refraction; the cleavage is well defined; and the optic axial angle is 25° . The sp. gr. is 2.77; the m.p. near 800° ; and the mol. ht. of soln. in hydrochloric acid is 36 cal. The salt is decomposed by a soln. of carbon dioxide, and dissolved by dil. acids. It is also decomposed superficially by water: $\text{Ca}_2\text{SiO}_4 \cdot \text{CaCl}_2 + \text{H}_2\text{O} = 3\text{CaO} \cdot \text{SiO}_2 + 2\text{HCl}$, followed by the hydration of $3\text{CaO} \cdot \text{SiO}_2$ as indicated above. A. Gorgeu obtained crystals of **calcium chlorometasilicate**, $\text{CaSiO}_3 \cdot \text{CaCl}_2$, along with those of the chlororthosilicate by the reaction just indicated. It forms regular hexagonal plates; the two optic axes approach very closely to one another. The chemical characters of the chlorometasilicate are like those of the chlororthosilicate, but the former is insoluble in a 5 per cent. soln. of acetic acid.

According to B. Karandéff, the eutectic point in mixtures of calcium metasilicate and calcium chloride lies close to the m.p. of calcium chloride, and 8° below it. Solid soln. may be formed up to 10 mols. per cent. CaCl_2 . There is no evidence of the formation of additive compounds. A. Woloskoff found that the system BaSiO_3 – BaCl_2 forms a eutectic with the m.p. 902° when the m.p. of barium chloride is 968° . The eutectic has 8 molar per cent. of barium metasilicate. In the system BaSiO_3 – BaS , there is a eutectic with 25 molar per cent. of barium sulphide at 1325° . Barium sulphide alone does not melt, and with the mixture BaSiO_3 – FeS , there is a liquation of ferrous sulphide, until 10 molar per cent. of ferrous sulphide remains in the barium metasilicate.

The **calcium phosphatosilicates** have been treated in connection with calcium phosphate. F. E. Wright²² obtained a mineral from Velardena, Mexico, which

was named *spurrite*—after J. E. Spurr; the analyses correspond with **calcium carbonatodiorthosilicate**, $2\text{Ca}_2\text{SiO}_4 \cdot \text{CaCO}_3$. F. W. Clarke represents it constitutionally:

The sp. gr. is 3.014 at 25°; the hardness 7; the refractive indices $\alpha=1.640$, $\beta=1.674$, $\gamma=1.679$ with sodium light; the double refraction $\gamma-\alpha=0.039$, and $\beta-\alpha=0.034$. It is decomposed by hydrochloric acid with the separation of gelatinous silica. For the synthesis of *spurrite*, *vide infra*, W. Eitel on the action of calcite on nephelite.

The analyses by A. E. Nordenskjöld, and G. Lindström, of a fibrous chalk-white mineral found in the Bjelke mine near Areskutan, Sweden, correspond with tetradecahydrated **calcium sulphatocarbonatometasilicate**, $\text{CaSiO}_3 \cdot \text{CaSO}_4 \cdot \text{CaCO}_3 \cdot 13\text{--}15\text{H}_2\text{O}$; and it was named *thaumasite*—from *θαυμάσιος*, to be surprised—in allusion to its remarkable composition. It has also been found in New Jersey, and in Utah. Analyses were also reported by O. Widman, F. Pisani, R. P. D. Graham, S. L. Penfield and J. H. Pratt, H. Backström, and B. S. Butler and W. T. Schaller. The mineral is either hexagonal or tetragonal. The sp. gr. is between 1.870 and 1.877, and the hardness 1.5–3.5. The soft mineral hardens on exposure to air. F. Zambonini found that 13 mols of water are lost at 112°; another mol at 158°–160°; and the last mol is driven off at 200°. S. L. Penfield found that at

	112°	205°	
Hours' heating	17	71	478
Percentage loss of water	11.59	13.41	14.96
			5
			280
			1000
			11.22
			19.18
			21.55

H. E. Merwin emphasized how 14 of the 15 mols of water are expelled more readily than the remaining mol. There is a distinct prismatic cleavage. The indices of refraction determined by E. Bertrand, A. Michel-Lévy and A. Lacroix, H. Backström, etc., range from B. S. Butler and W. T. Schaller's $\omega=1.500$, $\epsilon=1.461$, to S. L. Penfield and J. H. Pratt's $\omega=1.519$, $\epsilon=1.476$. The double refraction is high. The mineral is optically uniaxial and negative. G. Lindström said that the material analyzed was homogeneous under the microscope; this was confirmed by E. Cohen. E. Bertrand said he identified calcite, gypsum, and a third mineral, probably wollastonite, in thaumasite, hence he regards it as a mixture. A. E. Nordenskjöld said that E. Bertrand's sample was very impure. C. F. Rammelsberg represented thaumasite as a double salt, $(\text{CaCO}_3 \cdot \text{CaSiO}_3) + \text{CaSO}_4 + 15\text{H}_2\text{O}$. P. Groth represented the composition graphically:

E. F. Holden's measurement of the refractivity fits the assumption that it contains two hydroxyl groups. A hydrogel form is known, and C. Doelter and F. Cornu consider that a hydrogel like plombarite, $\text{CaSiO}_3 \cdot n\text{H}_2\text{O}$, has adsorbed calcium carbonate and sulphate.

Complex alkaline earth silicates.—

A. Haacke,²³ and R. Schwarz studied the binary system $\text{Li}_4\text{SiO}_4\text{--Ca}_2\text{SiO}_4$, and the f.p. curves are shown in Fig. 75. It appears as if two **lithium calcium orthosilicates** were formed, $2\text{Li}_4\text{SiO}_4 \cdot 3\text{Ca}_2\text{SiO}_4$, and $3\text{Li}_4\text{SiO}_4 \cdot 2\text{Ca}_2\text{SiO}_4$, with the respective m.p. 1104° and 1092°. He added that it is probable that the compound $\text{Li}_4\text{Ca}_2(\text{SiO}_4)_2$, or $\text{Li}_2\text{CaSiO}_4$, is formed, but decomposed at the higher temp. into the 2:3 and 3:2 silicates. This assumption agrees with the breaks in the cooling curves, with the microscopic appearance of sections of the cooled products, and with the sp. gr. which are:

Ca_2SiO_4	0	10	20	30	40	50	60	100	per cent.
Sp. gr.	2.280	2.400	2.423	2.424	2.591	2.847	2.566	2.970	

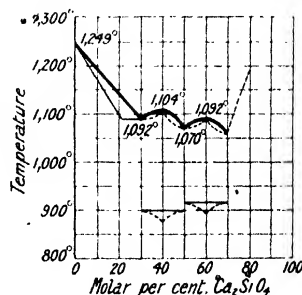

FIG. 75.—Binary System:
 $\text{Li}_4\text{SiO}_4\text{--Ca}_2\text{SiO}_4$.

R. C. Wallace studied the thermal diagram of mixtures of calcium and lithium metasilicates; and the results are summarized in Fig. 75. There is a gap in the miscibility roughly from 27-83 per cent. calcium metasilicate; and with from 40-80 per cent. calcium metasilicate there is a eutectic crystallization effect at 979°. The eutectic contains 50 per cent. calcium metasilicate. The sp. gr., mol. vol., and the f.p. represented by the temp. at which crystallization begins, are, for different percentages by weight of calcium metasilicate :

CaSiO ₃	0	10	30	50	60	70	80	90	100
Sp. gr.	2.61	2.64	2.72	2.80	2.80	2.84	2.85	2.88	2.91
Mol. vol.	34.64	34.87	35.62	36.36	37.30	37.74	38.62	39.30	40.00
F.p.	1168°	1147°	1083°	979°	1056°	1214°	1252°	1315°	1502°

C. J. Peddle studied the glasses with SiO₂-CaO-Na₂O; with SiO₂-CaO-K₂O; with SiO₂-CaO-K₂O-Na₂O; and with SiO₂-BaO-K₂O or Na₂O. R. C. Wallace's f.p. diagram for mixtures of sodium and calcium metasilicates, Fig. 76, has a

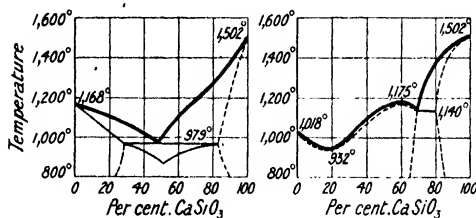

FIG. 76. —Freezing-point Curves of Binary Mixtures of Calcium Metasilicate with Lithium and Sodium Metasilicates.

maximum at 1175° corresponding with **sodium tricalcium pentametasilicate**, 2Na₂SiO₃·3CaSiO₃. N. V. Kultaschew gave 1160° for the m.p. The f.p. are :

CaSiO ₃	0	20	30	50	58.8	65	75	85	100
F.p.	1018°	932°	1024°	1143°	1175°	1165°	1140°	1449°	1502°

N. V. Kultaschew also investigated the f.p. curves of sodium and potassium metasilicates, and he isolated the compound 2Na₂SiO₃·3CaSiO₃ in monoclinic twin crystals. He obtained mixed crystals of **sodium dicalcium pentametasilicate**, 3Na₂SiO₃·2CaSiO₃, with another silicate. The latter was removed by boiling with water.

F. von Kobell found a fibrous mineral at Mount Baldo in Tyrol and named it **pectolite**—*πηκτός*, composed of pieces firmly joined together, *λίθος*, a stone—in reference to its structure. A. Breithaupt called a similar mineral **photolite**—*φῶς*, light, in reference to its phosphorescent qualities; and another mineral from Wolfstein, Bavaria, he called **osmelite**—*ὀσμή*, smell—in reference to its odour when breathed upon. J. Adam showed that osmelite and pectolite are the same minerals, although E. Riegel maintained that they are different. F. von Kobell, however, said that E. Riegel must have had some other mineral in hand. T. Thomson described a mineral **stellite** which occurs in radiant aggregates at Kilsyth, Stirlingshire, and R. P. Greg and W. G. Lettsom considered it to be natrolite, but J. D. Dana showed that the stellite from Bergen Hill, New Jersey, is pectolite. T. Thomson's **soda table-spar** is probably pectolite. The **walkerite** of M. F. Heddle, from Costorphine Hills, is probably pectolite. The **ratholite** of R. P. Greg and W. G. Lettsom from Ratho Quarry and Castle Rock, near Edinburgh, is probably pectolite. J. F. Williams reported a **manganopectolite** from Arkansas with 4 per cent. MnO.

The occurrence of the mineral in Tyrol has been discussed by G. A. Kenngott, L. Liebenor and J. Vorhauser, J. R. Blum, V. von Zepharovich, A. Cathrein, J. Lemberg, and F. von Kobell; in Silesia, by M. Websky, B. Schubert, and A. von Lasaulx; in Scotland, by

M. F. Heddle, R. Jameson, A. J. Scott, T. Thomson, etc.; in Sweden, by J. L. Igelström; in Canada, by G. C. Hoffmann; in Greenland, by O. B. Bøggild, and A. H. Chester; in the United States, by V. M. Goldschmidt, J. D. Dana, A. des Cloizeaux, J. F. Williams, E. F. Smith and E. B. Knorr, F. W. Clarke, J. D. Whitney, A. Leeds, etc. Analyses have been made by F. von Kobell, J. Lemberg, A. Breithaupt, M. F. Heddle, R. S. Houghton, J. Young, A. L. Parsons, J. L. Igelström, J. D. Whitney, F. W. Clarke and G. Steiger, F. W. Clarke, A. S. Eakle, E. F. Smith and E. B. Knorr, L. C. Beck, A. B. Meyer, O. B. Bøggild, E. Reuning, J. F. Williams, etc. According to J. J. Berzelius, some specimens contain fluo^urine.

The older analyses were found by C. F. Rammelsberg to give a ratio Na:Ca = 1:1.9 to 1:2.4; and $\text{Na}_2\text{O}:\text{SiO}_2 = 1:3$ to $1:5.7$. More recent analyses by G. Tschermak gave Na:Ca:Si = 1:1.9:3.1, and by F. W. Clarke, 1:2.1:3.1. This is in agreement with the formula $\text{NaCa}_2\text{HSi}_3\text{O}_6$ —**sodium calcium hydro-trimetasilicate**. G. A. Kenngott, and P. Groth assumed that the contained water is constitutional. C. Doelter found a sample lost 4.09 per cent. of water when strongly heated; while the fresh powder for 14 days over sulphuric acid lost 0.405 per cent.; at 100° , 0.09 per cent.; at 200° , 0.128 per cent.; and at 300° , 0.959 per cent. P. A. Bolley, and A. von Schulten obtained substances resembling pectolite in composition by adding lime-water to a soln. of sodium silicate. J. N. von Fuchs, and C. G. C. Bischof treated calcium carbonate with sodium silicate and obtained a pectolitic substance. J. Lemberg obtained similar results by the action of octohydrated sodium metasilicate on datolite, or wollastonite, or gypsum, or calcium carbonate for 78–100 hrs. at 190° – 200° . J. Lemberg also obtained an analogous product by the action of a soln. of calcium chloride on sodium silicate. C. Doelter also obtained a pectolite product by heating a mixture of silica, sodium carbonate, and lime in the proportions required for $\text{Na}_2\text{CaSi}_2\text{O}_6$. C. Doelter's product does not appear on the thermal diagram, Fig. 75. E. Baur succeeded in the synthesis of substances with the optical properties of pectolite in needle-like crystals, by heating to 400° – 450° , mixtures of silica, alumina, soda, lime, and water. He also obtained *potash-pectolite* by substituting potash for soda. J. Lemberg converted okenite (*q.v.*) into pectolite by the action of sodium silicate. H. Rosenbuch and E. Wülfing, J. Lemberg, F. Cornu, and E. Baur have discussed the formation of pectolite in nature.

Observations on the crystals of pectolite were made by A. Arzruri, R. P. Greg and W. G. Lettson, A. des Cloizeaux, P. Groth, C. F. Rammelsberg, A. L. Parsons, G. A. Kenngott, J. F. Williams, A. Michel-Lévy and A. Lacroix, M. F. Heddle, etc. J. D. Dana showed that pectolite is a monoclinic mineral with axial ratios $a:b:c = 1.1141:1:0.9864$ and $\beta = 84^\circ 40'$. A. Breithaupt gave 2.799–2.833 for the sp. gr.; M. F. Heddle gave 2.712–2.881; V. M. Goldschmidt, 2.880; J. F. Williams, 2.845; F. W. Clarke, 2.873; and A. B. Meyer, 2.85–2.86. The hardness is about 5. A. Michel-Lévy and A. Lacroix gave 1.61 for the mean refractive index; 0.038 for the dispersion; and 15° for the optic axial angle. W. W. Coblenz observed no bands near to those of water in the ultra-red transmission spectrum of pectolite; the reflection spectrum has maxima at 9.4μ , 10.3μ , and 10.8μ . The mineral is triboluminescent and it phosphoresces when exposed to radium. F. W. Clarke found that water in contact with pectolite acquires an alkaline reaction. G. Steiger found that after a month's contact with the mineral from Bergen Hill, water contained 0.57 per cent. of Na_2O . Uncalcined powdered pectolite was found by F. W. Clarke and G. Steiger to give to water 2.98 per cent. of silica, 0.30 per cent. of CaO, and 0.81 per cent. of Na_2O , after 14 hrs.' boiling; whereas with calcined powdered pectolite, after 4 hours' action, 3.03 per cent. silica, 0.10 per cent. CaO, and 1.50 per cent. Na_2O were dissolved. Hence they concluded that the action of water is not one of simple dissolution. F. W. Clarke and G. Steiger found that in contact with ammonium chloride, pectolite gives a product $\text{R}'_2\text{Ca}_2\text{Si}_3\text{O}_6 \cdot 6\text{H}_2\text{O}$, where R' is approximately two-thirds NH_4 , and one-third sodium. This makes it appear as if an *ammonia-pectolite* was formed. They also found that a soln. of 250 grms. of sodium carbonate in a litre of water extracts

8.68 per cent. of silica, or one-sixth the total amount from pectolite dehydrated by calcination. This is taken to indicate that the mineral is an acid metasilicate, $\text{HNaCa}_2\text{Si}_3\text{O}_9$. Before ignition, sodium carbonate soln., or even distilled water, has a slow decomposing action, both silica and bases being withdrawn. J. Roth discussed the transformation of pectolite into talc; and J. Lemberg effected the transformation of wollastonite into a substance resembling *spadaite*, $\text{H}_3\text{Mg}_2\text{Si}_3\text{O}_{21}$, by the prolonged action of soln. of magnesium chloride or sulphate. G. Steiger heated a mixture of powdered pectolite and silver nitrate in a sealed tube for 22 hrs. at $240^\circ\text{--}280^\circ$, and obtained a kind of *silver-pectolite*.

In 1784, C. Rinman²⁴ described the occurrence of a zeolite at Hällestå, Sweden, and C. C. von Leonhard referred to it as the *zeolithus lamellaris* of J. Müller. M. F. R. d'Andrada designated a specimen from Utö, Sweden, as *ichthyophthalmite*—from *ixthys*, fish; *ὀφθαλμός*, eye—in reference to the mother-of-pearl lustre. A. G. Werner called it *Fischauyenstein*. In 1801, R. J. Haüy referred to a sample from Iceland as *mesotype époincée*. J. N. von Fuchs and C. Gehlen showed the identity of the mineral with apophyllite. In 1805, R. J. Haüy called it **apophyllite**—*ἀπό*, away from; *φύλλον*, a leaf—in allusion to its tendency to exfoliate before the blowpipe flame. A. G. Werner investigated samples from Orawiezia, Aussig, and the Faröe Islands, and he called the mineral *albin*—*albus*, white. D. Brewster called a white specimen from the Faröe Islands *tessellate*, because it had a tessellated structure in polarized light. D. Brewster called a pale green specimen found in petrified wood at the Oxhaver Springs, Husavik, Iceland, *oxhaverite*. It was also investigated by E. Turner, and A. des Cloizeaux. G. S. von Waltershausen called an olive-green sample from Sicily, *xylochlore*—from *ξύλον*, wood; *χλωρός*, green. Both minerals were shown by G. A. Kenngott to be apophyllites. Specimens from Skye, Andreasberg, etc., showing alternate white and violet-black rings in polarized light were called by J. F. W. Herschel *leucocyclite*—*λευκός*, white; *κύκλος*, circle—and *chromocyclite*—*χρῶμα*, colour—by W. Klein. The mineral *louisite*, $\text{CaSi}_3\text{O}_7 \cdot 2\text{H}_2\text{O}$, reported by D. Hoenemann, was named after H. Louis. It was shown by T. L. Walker and A. L. Parsons to be a mixture of radiating quartz and cleavable apophyllite.

The apophyllite in various German provinces has been described by K. Busz, G. Cesaro, A. des Cloizeaux, C. Doelter, A. Frenzel, J. Fromme, G. Greim, C. W. von Gümbel, J. F. L. Hausmann, G. A. Kenngott, A. Knop, A. Koch, A. von Lasaulx, J. E. Hibsch, G. Leonhard, O. Lueddecke, C. F. Peters, H. Pohlg, C. F. Rammelsberg, F. A. Roemer, J. Rumpf, F. Sandberger, J. Schill, A. Schrauf, H. Stöling, A. Streng, H. Traube, M. Welsky, E. Weinschenk, A. Weisbach, A. von Zepharovich, G. Zimmermann, etc. In the Tyrols, by E. Buschiori, C. G. C. Buschof, J. R. Blum, A. des Cloizeaux, J. D. Dana, H. Dauber, C. Doelter and E. Mattersdorf, C. Gehlen, G. A. Kenngott, J. Lemberg, L. Liebenor and J. Vorhauser, O. Lueddecke, A. Pichler, F. von Richthofen, J. Rumpf, A. Schrauf, G. Tschermak, etc. In Switzerland, by P. Groth, and G. A. Kenngott. In Russia, by P. P. Pilipenko. In Italy, by E. Artini, L. Colomba, G. Leonhard, E. Manasse, I. Mechinelli and A. Balestra, J. Rumpf, L. Sipocz, S. J. Thugutt, D. F. Wiser, etc. In France, by A. Daubrée, A. Dufrenoy, F. Gonnard, etc. In Great Britain, by R. P. Greg and W. G. Lettsom. In Norway and Sweden, by J. J. Berzelius, W. C. Brögger, C. Gmelin, G. Hallberg, A. Hennig, L. J. Igelström, G. Leonhard, C. C. von Leonhard, C. F. Rammelsberg, C. Rinman, G. Seligmann, P. C. Weibye, etc. In the Faröe Islands, by J. J. Berzelius, D. Brewster, G. Leonhard, J. Rumpf, etc. In Iceland, by D. Brewster, P. Groth, G. A. Kenngott, G. Leonhard, E. Turner, G. S. von Waltershausen, etc. In Greenland, by C. Gmelin, G. Leonhard, J. Rumpf, A. Schrauf, F. Stromeyer, etc. In Finland, by W. Beck. In Canada, by G. C. Hoffmann, and A. L. Parsons. In the United States, by H. Crejner, W. Cross and W. F. Hillebrand, J. D. Dana, J. Eymann, F. A. Genth, C. Hersch, C. Klein, E. B. Kneer and J. Schönfeld, J. Rumpf, B. Sadtler, A. Schrauf, J. L. Smith, F. Tammann, etc. In Mexico, by C. Klein, C. F. de Lander, S. J. Thugutt, etc. In Brazil, by P. A. von Sachsen-Coburg. In Africa, by L. Gentil (Algiers), and J. A. L. Henderson (S. Africa). In India, by J. R. Blum, P. Groth, S. Houghton, F. R. Mallet, J. Rumpf, etc. In Siberia, by G. Leonhard. In Japan, by K. Jimbo, and T. Wada. Analyses are also reported by most of these observers.

A. B. de Fourcroy and L. N. Vauquelin, and V. Rose made the earliest analyses of apophyllite. J. J. Berzelius reported the presence of fluorine. C. E. Friedel

reported ammonia, but no fluorine, in samples from Utö, and Andreasberg. He, however, did find fluorine in some samples. Observations on the fluorine in apophyllite were made by A. E. Nordenskjöld, C. F. Rammelsberg, and S. J. Thuggutt. The last-named showed that the water-content of the powdered mineral is smaller than when in lumps—presumably water is lost in the process of comminution. C. F. Rammelsberg found that water is not lost over sulphuric acid, or at 100°; but at 200°, the evolution of water begins, and about 4 per cent. was lost at 260°. C. Doelter found that about 45 per cent. of the water is lost at 240°, and 55 per cent. at 260°. C. Hersch found apophyllite from Bergen Hill lost

	100°	160°	200°	240°	275°	300°	Red heat.
Loss . . .	0.11	0.38	0.77	2.03	9.08	9.91	16.61 per cent.

L. Colomba found with another specimen

	100°	160°	200°	250°	270°	285°	325°	360°	400°
L_{OBS}	0.17	0.51	0.86	6.51	8.49	9.89	11.60	13.35	15.85 per cent.

The dehydration curve shows two well-defined breaks—one at about 200° and one at 285°. Observations were also made by A. Hennig, by F. Zambonini, and by C. Doelter. A certain proportion of the water loss by dehydration is reabsorbed from a moist atm. This is therefore regarded as water of crystallization. G. Stoklossa inferred that the 2 mols. of water in apophyllite are chemically combined, and the dehydrated mineral does not reabsorb the water as do the zeolites.

The composition of idealized apophyllite was represented by C. F. Rammelsberg by the formula $H_7K(Ca_4Si_3O_{24} \cdot 4\frac{1}{2}H_2O)$, i.e. as P. Groth puts it, $H_7KCa_4(SiO_3)_8 \cdot 4\frac{1}{2}H_2O$; C. F. Rammelsberg also used $R_2Ca(SiO_3)_2Aq.$, and C. Doelter regarded apophyllite as hydrated **potassium calcium hydrodimetasilicate**, $H_2(Ca,K)_2Si_2O_6 \cdot \frac{1}{2}Aq.$, or $(Ca,K)_2SiO_3 \cdot \frac{1}{2}H_2SiO_3 \cdot \frac{1}{2}Aq.$, or $Ca(H,K)_2(SiO_3)_2 \cdot H_2O$. E. Baschieri gave:

where R denotes Ca,K_2 , and possibly Na_2 and $(CaOH)_2$. G. Tschermak used $4(H_6Ca_2Si_3O_{11})H_8K_2Si_3O_{11}$; and F. W. Clarke regarded apophyllite, gyrolite, and okenite as salts of the acid, $H_6Si_2O_7$, and apophyllite becomes $H_4(Si_2O_7) \cdot Ca(Si_2O_7) \cdot H_2CaOH \cdot \frac{1}{2}$, where some of the univalent $CaOH$ -group may be replaced by potassium. J. Dalton obtained a precipitate which he seemed to regard as a double silicate of calcium and potassium by adding lime-water to a soln. of alkali silicate.

F. Wöhler, and C. Doelter obtained crystals of apophyllite by heating to 150°–160° the powdered mineral and water in a gun-barrel after treatment with carbon dioxide. If okenite be heated with potassium silicate and carbonated water to 200°, new crystals of okenite and apophyllite are formed. Similarly, if okenite, sodium carbonate, and aluminium chloride be heated to 220°, apophyllite is formed. A. Daubrée observed the formation of apophyllite in the masonry of the baths at Plombières. A. C. Becquerel covered a gypsum plate with a soln. of potassium silicate and, after the mixture had stood for some time, found that crystals of potassium calcium silicate were formed. The product was insoluble in water, and decomposed by hydrochloric acid. J. Lemberg obtained the double silicate by the action of calcium chloride on potassium silicate for 57 hrs. at 185°; also by digesting calcium carbonate and an aq. soln. of potassium silicate for 20 days at 100°. A. Duboin melted calcium oxide with potassium fluoride and silica, and obtained mixtures of crystalline products containing fluorine, or chlorine, if potassium chloride be used in place of the fluoride. He obtained **potassium pentacalcium tetrafluorohexametasilicate**, $K_2O \cdot 5CaO \cdot 6SiO_2 \cdot 4KF$. With baryta, the products were free from halogens. A. Streng studied the formation of apophyllite in nature by the action of carbonated waters on wollastonite: $2CaSiO_3 + CO_2 + 2H_2O = CaCO_3 + H_2CaSi_2O_6 \cdot H_2O$; and S. J. Thuggutt gave $8CaSiO_3 + 8H_2O + 4CO_2 + KF = 4CaCO_3 + 4(CaSi_2O_5 \cdot 2H_2O) \cdot KF$.

Apophyllite is colourless, white, pale yellow, red, or green. G. Suckow said that the red apophyllite of Andreasberg is coloured with cobalt fluoride. Measurements of the crystals have been made by J. F. L. Hausmann, J. Rumpf, H. Dauber, O. Luedecke, C. F. Rammelsberg, A. Streng, P. Groth, K. Busz, J. Schill, H. Traube, G. Flink, B. Jezek, A. Schrauf, A. Pichler, A. des Cloizeaux, P. I. Ploner, E. Artini, J. Königsberger, L. Meschinelli and E. Balestra, A. Dufrénoy, F. Klocke, W. C. Brögger, G. Seligmann, F. Tamnau, L. Gentil, etc. According to W. H. Miller, the crystals belong to the tetragonal system, and have the axial ratio $a:c = 1:1.2515$. E. Mallard's view is that the mineral is pseudo-tetragonal, but it is really a complex of lamellar twinned, monoclinic individuals. This was supported by H. Haga and F. M. Jäger's observations on the X-radiograms. J. Rumpf gave 40° for the optic axial angle. The cleavage is well marked. O. Mügge studied the percussion figures; F. Rinne, the corrosion figures; and J. Lehmann, the contraction crazing, and the hissing of the mineral with water. O. Luedecke gave 1.961 for the sp. gr.; C. Rinman, 2.377; O. B. Böggild, 2.379; G. d'Achiardi, 2.2; A. Russell, 2.31; J. Rumpf, 2.339; H. Credner, 2.37; and B. Sadtler, 2.5. Most of the material analyzed—*vide supra*—had also its sp. gr. determined. The best representative value is 2.3–2.4; the hardness is 4–5. The indices of refraction have been determined by A. des Cloizeaux, L. Gentil, K. Zimanyi, O. Luedecke, etc. For Na-light, the values range from $\omega = 1.5331$ – 1.5379 , and $\epsilon = 1.5356$ – 1.5414 ; for Li-light, $\omega = 1.5309$ – 1.5240 , and $\epsilon = 1.5332$ – 1.5404 ; for Tl-light, $\omega = 1.5405$; and $\epsilon = 1.5429$; and for Cs-light, $\omega = 1.5311$, and $\epsilon = 1.5335$. The birefringence $\epsilon - \omega = 0.002$ is weak and positive. A. Ehringhaus gave for light of wave-length λ , between 17.5° and 18° :

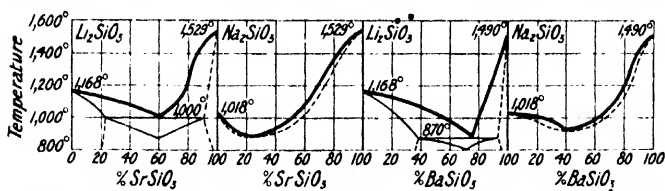

λ	690.7	623.9	589.3	513.2	491.6	435.7	404.7
ω	1.53108	1.53204	1.53437	1.53876	1.54032	1.54559	1.54959
ϵ	1.53257	1.53418	1.53555	1.53964	1.54101	1.54591	1.54962

The interference figures of the apophyllites are peculiar. Instead of showing the sequence of colours of Newton's rings characteristic of crystals in which the birefringence does not alter with wave-length, D. Brewster noted that in white light some varieties of apophyllite give rings with a different sequence—*e.g.* violet, greenish-yellow, and white circles alternating without any tint of red—*vide supra*, *chromocyclites*—or, as reported by J. F. W. Herschel, the rings may be black and white. These samples were called *leucocyclite* (*vide supra*). In some apophyllites, the birefringence is the same for red and yellow light, but other specimens may be positive, isotropic, or negative for differently coloured light. C. Klein showed that the apophyllite rings may be imitated by a combination of uniaxial positive and negative crystals. This supports the hypothesis that apophyllite is an isomorphous mixture of a positive and negative substance. The leucocyclite variety is positive; and C. Doelter showed that heating to 275° changes the rings of ordinary apophyllite to those of the leucocyclite variety—it is assumed that leucocyclite is a less hydrated variety. Many apophyllites exhibit in basal section a partition into sectors, some of which are biaxial and negative for blue and positive for red, with the axial planes crossed. Hence, argued H. A. Miers, apophyllite is an intergrowth of two or more silicates with different optical qualities. The subject has also been discussed by R. Brauns, C. Skoetsch, A. Ehringhaus, A. Wenzel, H. Michel, E. Mallard, F. Pfaff, F. Klocke, B. Trolle, etc. W. W. Coblenz found that the ultra-red transmission spectrum of apophyllite has water bands at 1.5μ and 2μ ; and the mineral is almost opaque between 3μ and 8μ . The reflection spectrum has the usual region common to silicates, and maxima at 9.15μ and 9.7μ . According to W. G. Hankel, the pyroelectrical properties of apophyllite are shown by cooling a crystal, when the ends and vicinities of the principal axes are positively electrified; and the intermediate region, negatively electrified. O. Weigel studied the electrical conductivity.

Powdered apophyllite was found by G. A. Kenngott, F. Cornu, and F. W. Clarke to have an alkaline reaction both before and after calcination. F. Wöhler observed

that apophyllite dissolves in water at 180° – 190° , and a press. of 10–12 atm. On cooling, the solute separates as crystalline apophyllite. Temp., said R. Bunsen, is the most important factor. C. G. C. Bischof found one part of apophyllite dissolves in 28,802 parts of water. C. Doelter found that after 14 days' action at 90° , distilled water dissolves only a trace of silica and lime; and after 21 days at 120° , 2.98 per cent. of matter was dissolved by the water, and of this, 64.2 per cent. was silica, and the remainder lime with an unweighable trace of potash. G. Spezia found that water at 25° and 1750 atm. press. dissolved no apophyllite (Poonah) after 6 months' action; some action occurred at 193° – 211° and at a press. of 14 atm. in 13 days; but not at 93° – 107° and 500–1056 atm. press. J. Lemberg treated apophyllite with soln. of magnesium sulphate or chloride in sealed tubes for periods extending from $4\frac{1}{2}$ hrs. at 180° to 3 mons. at ordinary temp. The lime was partially replaced by magnesia; and if soln. of alkali aluminate be used, then lime is also replaced by alumina; and with soln. of sodium silicate apophyllite passes into pectolite. F. W. Clarke studied the action of soln. of ammonium chloride and found that lime and alkali are removed. Apophyllite dissolves in acids with the separation of flocculent silica which E. Baschieri claimed to have the composition $H_2Si_2O_7$. F. Cornu found that hydrochloric, nitric, or sulphuric acid attacks the (111) and the (001) crystal faces strongly, but the (100) face was scarcely attacked. J. Samoiloff found that the alkali was extracted by plants from apophyllite about as easily as from leucite and orthoclase, but not so easily as from phillipsite. Natural transformations of apophyllite have been studied by F. Cornu, J. Roth, A. Himmelbauer, G. Tschermak, W. T. Schaller, A. Scheit, R. Gurgey, J. R. Blum, H. Michel, M. Websky, A. Streng, J. Konigsberger, F. von Richthofen, E. S. Dana, C. F. Peters, etc.

J. Dalton obtained a precipitate which appeared to be a *potassium barium silicate* by mixing baryta-water with a soln. of the alkali silicate. J. M. Ordway made some observations on the subject, and A. Duboin melted baryta with potassium fluoride and silica, and obtained **potassium dibarium trimetasilicate**, $K_2O \cdot 2BaO \cdot 3SiO_2$, of sp. gr. 3.78; and if this compound be fused with potassium chloride, the main product is **potassium heptabarium octometasilicate**, $K_2O \cdot 7BaO \cdot 8SiO_2$. J. M. Ordway heated mixtures of barium and sodium sulphates with silica and carbon and obtained products which he regarded as *sodium barium silicates*. The results of R. C. Wallace's observations on *lithium strontium silicates*, *lithium barium silicates*, *sodium strontium silicates*, and *sodium barium silicates* are summarized in Figs. 77–80. Lithium and strontium metasilicates

FIGS. 77–80.—Freezing-point Curves of Binary Mixtures of Strontium and Barium Metasilicates with Lithium and Sodium Metasilicates.

form mixed crystals with a lacuna between 22 and 92 per cent. of strontium silicate, and with lithium and barium metasilicates there is a lacuna with between 36 and 92 per cent. of barium silicate. Sodium metasilicate forms a continuous series of mixed crystals with both barium and strontium metasilicates.

According to A. de Schulten,²⁵ when lime-water is added to a conc. soln. of potassium silicate until a slight precipitate is formed, and the mixture is then heated in sealed tubes at 180° – 200° for 24 hrs., the gelatinous mass which forms on cooling encloses a small quantity of some substance crystallized in prismatic needles. If the tube is heated for several days with occasional agitation, the

gelatinous matter gradually disappears, and the quantity of the crystals increases. By repeated levigation, the plates of silica can be removed, and the prismatic crystals are then obtained, mixed with only a small quantity of hexagonal plates; the quantity of hexagonal plates increases, and that of the needles diminishes if the lime-water is added in too small a quantity; if, however, too much lime-water is added, no crystals are formed at all. The prismatic crystals are white, they have a nacreous lustre, melt before the blowpipe, and are decomposed by hydrochloric

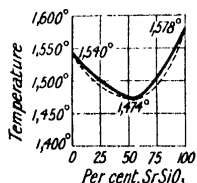

FIG. 81. - Freezing-point Curve of the Binary System: CaSiO_3 - SrSiO_3 .

acid with separation of gelatinous silica which retains the form of the original crystals. Analyses correspond with the triple salt dihydrated **sodium potassium calcium trimetasilicate**, $(\text{K}_2, \text{Na}_2, \text{Ca})\text{O} \cdot 3\text{SiO}_2 \cdot 2\text{H}_2\text{O}$. The soda is derived from the alkalis in the glass. P. Eskola found that calcium and strontium metasilicates form a complete series of mixed crystals with a minimum in the curve, Fig. 81, at $1474^\circ \pm 3^\circ$ and 56 per cent. SrSiO_3 . The mixed crystals are crystallographically like β - CaSiO_3 .

Mixtures of silica, baryta, and lime were fused into glasses by H. Benrath, G. Wagener, and C. F. Plattner. According to P. Lebedeff, calcium and barium metasilicates give an isomorphous series with a continuous f.p. curve, having a minimum at about 1000° with nearly 35 per cent. of barium metasilicate. A glass is obtained on cooling rapidly, while slowly cooled mixtures solidify to a homo-

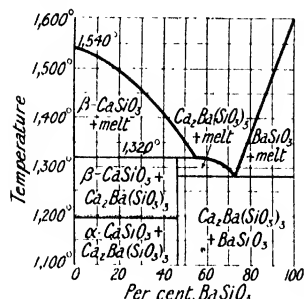

FIG. 82. - Freezing-point Curve of the Binary System: CaSiO_3 - BaSiO_3 .

geneous series of monoclinic solid soln., which do not disintegrate or undergo further change. P. Eskola, however, obtained the curves shown in Fig. 82. This diagram shows that a compound **barium dicalcium metasilicate**, $\text{BaCa}_2\text{Si}_3\text{O}_{10}$, is formed which has an incongruent m.p. at $1320^\circ \pm 4^\circ$, forming β -calcium metasilicate and liquid. The crystals of the compound are usually in the form of elongated fibres; they are uniaxial and negative; and probably hexagonal. The crystals have good cleavages in their prismatic zone. The indices of refraction for the F -, T l-, D -, and C -rays are respectively $\epsilon = 1.690, 1.685, 1.681$, and 1.677 ; and $\omega = 1.678, 1.672, 1.668$, and 1.664 .

An artificial blue pigment was used by the Egyptians from the time of the 4th dynasty, and was also used at the time of the Roman Empire. M. P. Vitruvius²⁶ said that the colour was made by heating a mixture of copper filings, soda, and sand. Observations on the colour were made by H. Davy, L. N. Vauquelin, J. P. J. d'Arcet and co-workers, W. J. Russell, F. C. J. Spurrell, W. Burton, H. le Chatelier, etc. H. de Fontenay found the percentage composition of an *Egyptian blue* body to be 70.25 per cent. SiO_2 ; 2.36, $\text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3$; 8.35, CaO ; 16.44, CuO ; and 2.83, Na_2O , with no trace of cobalt oxide. It can be made by heating a mixture of sand, 70; copper oxide, 15; whiting, 25; and soda ash, 6, below 1000° . F. Fouqué made a particular study of the colour, and considered it to be due to the formation of a **calcium cupric metasilicate**, $\text{CaO} \cdot \text{CuO} \cdot 4\text{SiO}_2$, or $\text{CaCu}(\text{Si}_2\text{O}_5)_2$. He prepared this quite free from alkali, and called it *Vestorian blue*. The calcium cupric silicate was obtained in azure-blue crystals. These results were confirmed by A. P. Laurie and co-workers. The crystals belong to the tetragonal system. The sp. gr. is 3.04 (F. Fouqué), 2.948 (A. P. Laurie). In convergent polarized light, said F. Fouqué, the crystals exhibit the characteristics of uniaxial minerals. The crystals are optically negative. They are remarkably pleochroic, being of a pale rose colour with rays vibrating parallel to the axis, and intensely blue with rays

vibrating perpendicular to that axis. The double refraction is 0.031. A. P. Laurie and co-workers found the refractive index of the ordinary ray is $\omega=1.6354$, and that of the extraordinary ray, $\epsilon=1.6053$, so that the double refraction is in agreement with F. Fouqué's value. H. le Chatelier, and G. Barth obtained a blue colour by heating a mixture of copper oxide or silicate, silica, and barium carbonate or silicate—with or without sodium carbonate. G. Barth also used strontium silicate in place of barium silicate. There is nothing here to show that the products are chemical individuals, *barium cupric silicate*, or *strontium cupric silicate*. The double silicates were also obtained by precipitation.

§ 26. Beryllium or Glucinum Silicates

Beryllium forms an anhydrous orthosilicate—*phenacite*—and a hemihydrated orthosilicate—*bertrandite*; the orthosilicate also forms a series of solid soln., with manganese, zinc, and ferrous silicates, known as *trimerite*. There is a dimorphous hydrated beryllium alkali silicate furnishing *eudidymit*, and *epidymite*; and a series of fluoriferous metasilicates—*leucophane* and *melinophane*. There are also the aluminosilicates exemplified by *beryl*. According to W. C. Brögger,¹ the minerals phenacite, trimerite, willenite, and diopside form a morphotropic family.

The mineral **phenacite** was discovered by N. von Nordenskjöld in the emerald mines near Tokowaja, Urals. The crystals had previously been mistaken for quartz—hence the name from *φάναξ*, a deceiver. It has also been found near Miask, Ilmen Mts.; Framont, Vosges Mts.; Reckingen, Switzerland; Darango, Mexico; Topaz Butte, Colorado; in New Hampshire, Virginia, etc. Analyses have been reported by N. von Nordenskjöld, C. G. C. Bischof, L. A. Aars, C. F. Rammelsberg, S. L. Penfield, E. S. Sperry, K. Vrba, K. Chroustchoff, G. Seligmann, etc. The results show that phenacite is **beryllium orthosilicate**, Be_3SiO_4 .

A. Daubrée synthesized phenacite by passing a current of silicon chloride over beryllia at a red heat; C. J. St. C. Deville, however, thought that the analysis of the product of this operation agreed more nearly with **beryllium metasilicate**, BeSiO_3 . G. Stein made the orthosilicate by fusing 2 mols of beryllia with a mol of silica in carbon or porcelain crucibles, and he obtained the metasilicate by heating a mixture of equimolar proportions at 1600°. J. J. Ebelmen fused silica and beryllia with borax, and obtained hexagonal crystals which E. Mallard found to have optical properties like phenacite. P. Hautefeuille and A. Perrey heated a mixture of silica, beryllia, and lithium vanadate and carbonate, or lithium molybdate for a long time at 600°–700°, and obtained well-defined crystals. C. Doelter made crystals of phenacite by melting beryllium nitrate and silica with ammonium fluoride as *agent minéralisateur*. W. Pukall made the meta- and ortho-silicates by heating intimate mixtures of beryllium hydroxide and silicic acid in theoretical proportions. F. M. Jäger and H. S. van Klooster made the metasilicate in a somewhat similar way.

Phenacite occurs in colourless, yellow, pale rose-red, or brown crystals. The crystals were examined by N. von Nordenskjöld, G. Rose, R. Hermann, G. Seligmann, E. Beyrich, A. des Cloizeaux, A. Russell, M. Websky, W. H. Miller, W. Phillips, M. Henglein, J. C. G. de Marignac, S. L. Penfield, W. E. Hidden, W. Cross, and W. F. Hillebrand, H. J. Burkart, L. Weber, etc. According to N. von Kokscharoff, the crystals belong to the trigonal system, and the axial ratio $a:c$ is 1:0.661, and M. Websky gave 1:0.661958. C. Doelter's crystals were short prisms. Penetration twinning occurs about the vertical axis; the cleavage is well marked. H. Haga and F. M. Jäger studied the X-radiograms of phenacite. A. von Lasaulx noted in the crystals liquid inclusions which still remain at 100°, and cannot therefore be liquid carbon dioxide. N. von Nordenskjöld gave 2.969 for the sp. gr.; A. Breithaupt gave 3.001; K. Chroustchoff, 2.945–2.986; and

W. Cross and W. F. Hillebrand, 2-967. According to G. Stein, the sp. gr. of the crystals of the orthosilicate is 2.46, and of the metasilicate 2.35. K. Chroustchoff gave 7-8 for the hardness. According to F. M. Jäger and H. S. van Klooster, the m.p. of the metasilicate is over 1750°; and, according to G. Stein, the m.p. of both silicates is over 2000°. G. Spezia melted the mineral in the oxyhydrogen blowpipe. A. des Cloizeaux, W. Haidinger, and A. Offret measured the indices of refraction. A. Offret obtained 0°:

	Li-line	Na-line	Green Cd-line	Blue Cd-line
ω	1.6509	1.6542	1.6570	1.6610
ϵ	1.6666	1.6700	1.6729	1.6770

A. des Cloizeaux observed that at 100°, the refractive index was increased by 0.00108. The birefringence is higher than that of quartz, the crystals are optically positive. A. Ehringhaus and H. Rose compared the dispersion and double refraction of the orthosilicates of zinc, beryllium, and copper with their mol. wts. W. Haidinger noted that the crystals are pleochroic, being colourless for the ordinary ray, and pale yellowish-brown for the extraordinary ray. T. Liebisch found the crystals phosphoresce feebly. W. G. Hankel, and C. Friedel and A. de Gramont studied the pyroelectricity of the crystals. Acids do not attack the mineral. F. Cornu said that phenacite moistened with water reacts feebly alkaline to litmus. W. Pukall found the meta- and ortho-silicates to be but slightly attacked by acids and alkalis.

According to G. Flink,² *trimerite* is a Swedish mineral whose analysis corresponds with *beryllium manganese orthosilicate*, BeMnSiO_4 ; or with a solid soln. of the orthosilicates of beryllium, calcium, and manganese. The triclinic crystals have the axial ratios $a:b:c = 0.5774:1:0.5425$; or, pseudohexagonal $a:c = 1:0.9424$. W. C. Brögger gave 3-474 for the sp. gr. The hardness is 6-7. The indices of refraction for Li-, Na-, and Tl-light are respectively $\alpha = 1.7119$, 1.7148 , and 1.7196 ; $\beta = 1.7173$, 1.7202 , and 1.7254 ; and $\gamma = 1.7220$, 1.7253 , and 1.7290 . The birefringence $\gamma - \alpha$ is 0.0105; and $\gamma - \beta$ is 0.0051. The optic axial angles $2H = 120^\circ 1'$, and $2V = 83^\circ 29'$.

The mineral **bertrandite** was found by E. Bertrand³ *des environs de Nantes*, and it was named by A. Damour. Occurrences have been described by A. Russell, H. L. Bowman, C. Baret, A. Lacroix, S. L. Penfield, O. C. Farrington and E. W. Tillotson, etc. Analyses reported by A. Damour, S. L. Penfield, P. P. Pili-penko, K. Vrba, and T. Vogt correspond with the idealized formula $\text{H}_2\text{Be}_2\text{Si}_2\text{O}_6$, or with **hemihydrated beryllium orthosilicate**, $\text{Be}_2\text{SiO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$, or, as P. Groth expresses it, with **beryllium dihydroxydisilicate**, $(\text{BeOH})_2\text{Be}_2\text{Si}_2\text{O}_7$, since water is evolved only at a red heat, and it is therefore probably present in hydroxylic form and not as water of hydration. Bertrandite is colourless or pale yellow, with a vitreous lustre. The crystals have been measured by E. Bertrand, S. L. Penfield, etc. K. Vrba showed that the rhombic crystals have the axial ratios $a:b:c = 0.56988:1:0.59442$. Twinning occurs with axes crossed at about 60° and 120° . The cleavage is perfect. The optic axial angles $2H = 118^\circ$; and $2V = 74^\circ 51' 34''$. E. Bertrand gave 2.593 for the sp. gr.; K. Vrba gave 2.5963-2.6008; R. Scharizer, 2.55; and S. L. Penfield, 2.598. The hardness is 6.0-6.5. The optical properties of the crystals have been examined by E. Bertrand, A. des Cloizeaux, R. Scharizer, K. Vrba, T. Vogt, S. L. Penfield, etc. The indices of refraction for Na-light are $\alpha = 1.5914$, $\beta = 1.6053$, and $\gamma = 1.6145$. The birefringence $\gamma - \alpha = 0.0231$. The optical character is negative. S. L. Penfield found the crystals are pyroelectric. According to F. Grünling, the *hessenbergite* of G. A. Kennigott, and the *siderozene* of F. Hessenberg are varieties of bertrandite.

A colourless and water-clear mineral found on the Island of Oevre-arö, Norway, was analyzed by W. C. Brögger,⁴ and A. E. Nordenskjöld. It appears to be **beryllium sodium hydromesotrisilicate**, $\text{NaBeHSi}_3\text{O}_8$. It was named *eudidymite*, from *εὐ*, easily; *διδυμος*, twin. The crystals are always twinned and of tabular habit. According to W. C. Brögger, it forms monoclinic crystals with the axial

ratios $a : b : c = 1.7108 : 1 : 1.1071$, and $\beta = 93^\circ 45\frac{1}{2}'$. The sp. gr. is 2.548, and the hardness under 6. The optic axial angle $2V = 31^\circ 4'$, and $2H = 29^\circ 43'$. The indices of refraction for red light, sodium light, and thallium light are respectively $\alpha = 1.54444$, 1.54533 , and 1.54763 ; $\beta = 1.54479$, 1.54568 , and 1.54799 ; and $\gamma = 1.54971$, 1.55085 , and 1.55336 . The water is but incompletely expelled even at a red heat; a blast flame is needed for its complete expulsion. It is rapidly and easily decomposed by hydrofluoric acid, but, calcined or uncalcined, it is incompletely decomposed by hydrochloric acid, and then only with difficulty. G. Flink, and H. Sjögren analyzed a white mineral from Narsasik, Greenland, and found it to have the same composition as eudidymite, but it furnishes rhombic crystals with the axial ratios $a : b : c = 1.7367 : 1 : 0.9274$. It was named *epididymite*. Beryllium sodium hydrotrisilicate is therefore dimorphous, but whether isomeric or polymeric is not known. The optic axial angle $2V = 31^\circ 4'$. The sp. gr. is 2.553; and the hardness 6. The indices of refraction for Na-light are $\alpha = 1.5645$, $\beta = 1.5685$, and $\gamma = 1.5688$. The behaviour of the mineral on heating, and towards acids resembles that of eudidymite.

According to P. Hautefeuille and A. Perrey, when the constituents of the alkali beryllium silicates are fused at 600° – 700° , with an excess of potassium vanadate, mineralization occurs. The product after washing with water and dil. potassium hydroxide, can be separated into crystalline constituents by a soln. of cadmium borotungstate of varying sp. gr. A series of *potassium beryllium silicates*, having $K_2O : BeO : SiO_2$ as $1 : 1 : 4$, $1 : 2 : 4$, $1 : 1 : 5$, and $1 : 2 : 5$, has been reported; similarly with *sodium beryllium silicates*, having $Na : BeO : SiO_2$ as $1 : 2 : 6$, $1 : 2 : 3$, $3 : 4 : 15$, $3 : 4 : 14$, and $3 : 4 : 18$. A. Duboin dissolved beryllia and silica in fused potassium fluoride, and submitted the product to a prolonged fusion with potassium chloride. He obtained products varying between $2K_2O : 3BeO : 7SiO_2$ and $2K_2O : 3BeO : 5SiO_2$.

C. W. Blomstrand⁵ described a mineral he found in the crystalline limestone of Langban, Sweden, which he called *barylite*—from *βαρύς*, heavy; *λίθος*, a stone. The composition corresponds with $Ba_4Al_4Si_7O_{24}$; and F. W. Clarke symbolized its composition $Al(Si_2O_7)_3 \cdot AlBa_3$. G. Aminoff, however, gave the formula $Be_2BaSi_2O_7$, and said that C. W. Blomstrand had mistaken beryllia for alumina in his analysis. This makes the mineral *barium diberyllium orthosilicate*. The mineral occurs in groups of white or colourless, prismatic crystals, more or less of tabular habit, and, according to M. Weibull, probably rhombic. G. Aminoff gave for the axial ratios of the rhombic crystals $a : b : c = 0.8025 : 1 : 0.8376$. There are two distinct cleavages, forming an angle of 84° . The optical axial angle $2V = 80^\circ 54'$. The sp. gr. is 4.027, and the hardness 7. The indices of refraction are $\alpha = 1.6911$, $\beta = 1.6957$, and $\gamma = 1.7028$; and the birefringence, according to E. Dittler, is $\gamma - \alpha = 0.014$. The optical character is positive. The mineral is not attacked by the ordinary mineral acids.

The mineral *helvite* or *helvine* was first described by F. Mohs,⁶ and named by A. G. Werner, from *fluo*, the sun, in allusion to its yellow colour. Analyses were made by H. A. von Vogel, C. G. Gmelin, C. F. Rammelsberg, N. Teich, N. von Kokscharoff, R. Haines, B. E. Sloan, W. C. Brögger, H. A. Miers and G. T. Prior, H. Bäckström, etc. The results have been discussed by C. F. Rammelsberg, who gave $(Mn, Fe)_3S_3(Be, Mn, Fe)_2SiO_4$; G. A. Kenngott gave $MnS_3R_2SiO_4$; V. M. Goldschmidt gave $3RBeSiO_4 \cdot RS$; and P. Groth, $(Be, Mn, Fe)_2S(SiO_4)_3$. W. C. Brögger and H. Bäckström made some observations on this subject. The idealized mineral is *beryllium sulphosilicate*, the actual mineral is a solid soln. with various other silicates. The mineral is usually yellow, brownish-red, or green. The crystals belong to the cubic system. The sp. gr., determined in many cases by those who analyzed the mineral, range from 3.165–3.383. The hardness is over 6. A. Michel-Lévy and A. Lacroix gave 1.739 for the refractive index. The pyroelectric properties were studied by W. G. Hankel, and J. and P. Curie. When treated with hydrochloric acid, hydrogen sulphide is evolved, and gelatinous silica is formed.

J. P. Cooke found a beryllium sulphosilicate in the granite of Rockport, Mass., which was called *danalite* after J. D. Dana. According to C. F. Rammelsberg, analyses by J. P. Cooke, F. A. Genth, and H. A. Miers and G. T. Prior correspond with $RS_3R_2SiO_4$; according to G. A. Kenngott, with $ZnS_3(Be, Fe, Mn)_2SiO_4$; and, according to P. Groth,

(Fe,Zn,Be,Mn)₈(SiO₄)₈. The sp. gr. is 3.427, and the hardness 5-6. With hydrochloric acid, hydrogen sulphide is evolved and gelatinous silica remains.

§ 27. Magnesium Orthosilicates

The mineral **forsterite** was first described by A. Lévy¹ in 1824. It was named after L. Forster. The mineral was found as crystals and crystal aggregates in Vesuvian lava. G. Strüver found it in the Baccano crater. Observations on Italian forsterite were also made by B. Mierisch, G. vom Rath, M. Bauer, F. Hessenberg and A. Seacchi, A. A. Lösch; N. von Kokscharoff reported it in a mine at Slataust, Urals; A. Knop, at Schelingen, Kaiserstuhl, Baden; A. Helland, at Snarum, Norway; and A. K. Coomaraswamy, at Kakgala, Ceylon. C. U. Shepard called a variety he found at Bolton, Mass., *boltonite*. Analyses were made by those just mentioned and by C. F. Rammelsberg, E. Weinschenk, K. Thaddeeff, F. Zambonini, H. Arsandaux, J. I. Smith, G. J. Brush, etc. E. Cohen found the mineral in a meteorite from Los Muchachos. The results correspond with **magnesium orthosilicate**, Mg_2SiO_4 . J. J. Ebelmen reported that he synthesized crystals of forsterite, *qui présentent exactement les mêmes faces que les cristaux du péridot du Vésuve*, by fusing a mixture of boric oxide, silica, and magnesia. The boric oxide simply served as a solvent of relatively low m.p., and it was evaporated by a protracted heating at a high temp. G. Lechartier fused silica and magnesia along with calcium chloride; and P. Hautefeuille operated

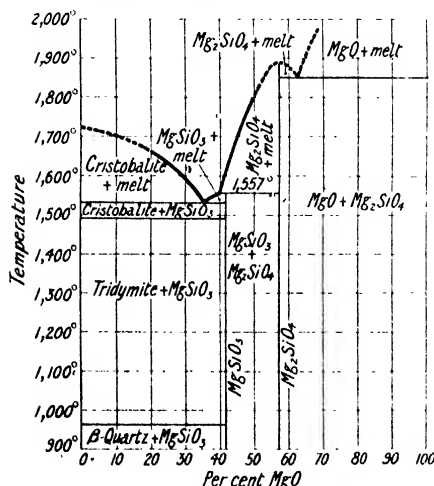

Fig. 83.--Thermal Diagram of the Binary System: MgO-SiO₂.

with the same oxides and magnesium chloride. S. Meunier heated magnesium vapour to redness in a mixture of steam and silicon chloride. N. G. Sefström, W. A. Lampadius, J. A. Hedvall, and P. Berthier heated various mixtures of magnesia and silica, and obtained more or less devitrified enamels. J. W. Cobb noted that the reaction begins below the m.p. of either component. W. Pukall also obtained the orthosilicate by heating an intimate mixture of magnesia and silicic acid. G. Stein fused a mixture of the constituents at a temp. exceeding 2000° in an electrically heated carbon tube furnace, and obtained crystals which *mit dem des Minerals Forsterit übereinstimmt*. The f.p. curves of mixtures of silica and magnesia have been studied by N. L. Bowen and O. Andersen. The results are indicated in Fig. 83. Both the ortho- and the meta-silicates can exist

in contact with the liquid. The maximum corresponding with the orthosilicate is at $1890^{\circ} \pm 20^{\circ}$; and the eutectic with magnesium oxide and the orthosilicate is at $1850^{\circ} \pm 20^{\circ}$, at which the mixture has 14 per cent. of magnesia, and 86 per cent. of the orthosilicate. The eutectic with silica and magnesium metasilicate as solid phases has 12.5 per cent. of the former, and 87.5 per cent. of the latter, and the temp. is $1513^{\circ} \pm 20^{\circ}$. For the colloidal magnesium silicates, *vide supra*, water-glass.

The crystals of forsterite belong to the rhombic system. They have been studied by W. H. Miller, G. vom Rath, F. Fouqué and A. Michel-Lévy, V. Goldschmidt, E. T. Allen and co-workers, A. Scacchi, F. Hessenberg, G. Strüver, N. von Kokscharoff, etc. M. Bauer gave for the axial ratios $a:b:c=0.46476:1:0.58569$. The cleavage after the (001) and the (010) faces is perfect. The optic axial angle is large, being 86° . G. vom Rath gave 3.191 for the sp. gr. of forsterite; C. F. Rammelsberg, 3.243; K. Thaddeff, 3.223; N. von Kokscharoff, 3.191; A. Helland, 3.22; J. L. Smith, 3.208-3.328; H. Arsandaux, 3.248; and E. Cohen, 3.199. The natural crystals usually contain a little iron; H. Backlund's sample from Slatoust was very low in iron, and its sp. gr. was 3.191. J. J. Ebelmen's synthetic forsterite had a sp. gr. 3.237; N. L. Bowen and O. Andersen's, 3.216 ± 0.002 ; G. Stein's, 3.21; and G. Lechartier's, 3.22. The hardness of forsterite is between 4 and 5. N. L. Bowen and O. Andersen gave $1890^{\circ} \pm 20^{\circ}$ for the m.p.; G. Stein said the m.p. is below 1900° . A. S. Deleano gave 1600° for the m.p.; C. Doelter, 1700° for the m.p., 1655° for the f.p., and 1785° for the temp. of formation. The indices of refraction have been determined by A. des Cloizeaux. H. Backlund found for Na-light with a sample from Slatoust, $\alpha=1.6361$, $\beta=1.65185$, and $\gamma=1.66975$. N. L. Bowen and O. Andersen gave $\alpha=1.635$, $\beta=1.661$, and $\gamma=1.670$; and birefringence 0.035 for Na-light; and E. T. Allen and co-workers gave $\alpha=1.645$, $\beta=1.656$, and $\gamma=1.668$ all ± 0.003 ; and birefringence 0.023. The crystals extinguish parallel to the cleavage directions. The crystals are decomposed by hydrochloric acid with the separation of gelatinous silica—*vide olivine*. W. Pukall said that his product gained only 2.58 per cent. after lying in water for 70 days.

It is really difficult to obtain minerals quite free from iron. The colours, ranging from pale cream, yellow, red, and brown to black, are usually produced by iron oxide as the predominant tinctorial agent, for, as R. J. Haiiy remarked: "When Nature takes up her brush, iron is almost always on her palette." Forsterite may be white, yellowish-white, greyish-white, or greenish-white, and it sometimes becomes yellow on exposure to air, owing to the oxidation of the "ferrous" iron. The white and colourless crystals—*e.g.* those from Vesuvius—have been also called *white olivine*, or *white peridot*. The ferrous oxide in the published analyses of forsterite ranges from 0.22 up to 4.56 per cent.; with higher proportions, the mineral passes into chrysolite or olivine. There is, however, no sharp line of demarcation. It would appear as if fayalite, Fe_2SiO_4 , and forsterite, Mg_2SiO_4 , are the terminal members of a continuous series of solid soln.

Near the beginning of the present era, *chrysolite*— $\chi\rho\sigma\iota\tau\acute{o}\varsigma$, gold; $\lambda\theta\omicron\varsigma$, a stone—was referred to by Pliny in his *Historia naturalis* (37. 42), and it is thought to refer to what is now called topaz, and his topaz refers to the present-day chrysolite. Some varieties of both are used as gem-stones. Chrysolite was referred to by the older writers: J. G. Wallerius,² A. J. d'Argenville, A. Cronstedt, J. B. L. Romé de l'Isle, and F. de St. Fond. A. G. Werner applied the name *olivine*, in reference to the olive-green colour of many specimens. According to R. J. Haiiy, the term *peridot* is of unknown derivation, but it had been used for a long time by the French jewellers for chrysolite. He showed that the three names referred to the one mineral. G. Romanovsky's *glinkite* was shown by W. Beck to be nothing but chrysolite or olivine. V. Iskyul studied the action of hydrochloric acid on glinkite. The term olivine is used not only for a specific mineral, but also for a group of ferromagnesian orthosilicates of the general formula $\text{R}''_2\text{SiO}_4$. The family includes *forsterite*, Mg_2SiO_4 ; *monticellite*, CaMgSiO_4 ; *olivine peridot*, or *chrysolite*,

$(\text{Mg,Fe})_2\text{SiO}_4$; *hortonolite*, $(\text{Fe,Mg,Mn})_2\text{SiO}_4$; *fayalite*, Fe_2SiO_4 ; *tephroite*, Mn_2SiO_4 ; and *roeppeite*, $(\text{Fe,MnZn})_2\text{SiO}_4$. Calcium orthosilicate is sometimes called *lime-olivine*.

Olivine is an essential constituent and characteristic mineral of many basic rocks. It is commonly developed in the less siliceous magmas and lavas. It is rarely found crystallized on a large scale, but well-defined, small crystals are common in basic eruptive rocks like basalt, limburgites, peridotites, and gabbros. It is less common in trachytes, andesites, and dacites. Olivine is the predominant mineral in some ultra-basic rocks, and, associated with diallage or bronzite, may form an olivine-rock. At the Dun Mt. in New Zealand, it is associated with chromite, forming a mass of rock called *dunite*. Olivine is a common constituent of meteorites. Numerous analyses have been reported.³ The silica in the analyses ranges from 36.72-42.81 per cent.; the magnesia, from 28.48-51.64 per cent.; and the ferrous oxide, from 5.01-29.96 per cent. If the formula be $(\text{Mg,Fe})_2\text{SiO}_4$, the ratio Mg:Fe ranges from 9:1 to about 2:1. G. Cesaro agreed with G. Tschermak in considering olivine to be an oxymetasilicate:

A. Damour⁴ described a *péridot titanifère*, or *titanolivine*, of a deep yellow or red colour containing 5-6 per cent. TiO_2 . It was discussed by A. Lacroix, and L. Brugnatelli; its composition is represented $(\text{Mg,Fe})_2(\text{Si,Ti})\text{O}_4$.

P. Berthier⁵ first synthesized olivine by simply fusing a mixture of the constituent oxides. F. Fouqué and A. Michel-Lévy obtained it by fusing a mixture of magnesia, silica, and ferrous ammonium sulphate; A. Daubrée, by recrystallization from fused meteorites, magnesian eruptive rocks, and serpentine; and also by the partial oxidation of an iron silicide and subsequent fusion of the product: V. Pöschl, fused mixtures of silica, iron carbonate, and magnesium carbonate. He also made a partial study of the binary system, Mg_2SiO_4 - Fe_2SiO_4 (*vide infra*), and of the ternary system, Mg_2SiO_4 - Fe_2SiO_4 - Ca_2SiO_4 . C. Doelter made olivine by fusing hornblende with calcium and magnesium chlorides; G. Lechartier, by fusing silica, magnesia, and calcium chloride and some iron compound; P. Hautefeuille, by fusing silica, magnesia, and magnesium chloride in a similar way; and likewise also J. J. Ebelmen, by fusing together silica, magnesia, iron oxide, boric acid, and potassium tartrate. H. H. Reiter fused mixtures of albite, nephelite, augite, olivine, and magnetite in different proportions, and observed that olivine separates along with several other minerals when the mass cools. C. Doelter obtained olivine among the products of the fusion of biotite, vesuvianite, tourmaline, clinchlore, and garnet. G. vom Rath found some crystals of olivine formed in the mantle of a blast furnace; P. W. Jereméeff, in some cast-iron; and J. H. L. Vogt, and F. W. Rösberg, in some blast furnace slags.

The colour of olivine is commonly olive-green, but it is sometimes brownish or greyish-red, or greyish-green; and its colour may change on exposure to air owing to oxidation of the ferrous iron. The lustre is usually vitreous. The crystals have been measured by G. vom Rath,⁶ V. von Zepharovich, A. Scacchi, H. Traube, G. Rose, F. A. Quenstedt, W. Haidinger, M. F. Heddle, etc. The crystals belong to the rhombic system, with axial ratios $a:b:c=0.4658:1:0.5865$. A. des Cloizeaux found the optic axial angle to be $87^\circ 46'$. F. Rinne and co-workers, N. Alsen and G. Aminoff, and C. Berndt have obtained the **X-radiogram** of olivine; but the space-lattice has not been established. According to C. Berndt, the elementary parallelepiped has the dimensions $a=4.84 \times 10^{-8}$ cm., $b=10.40 \times 10^{-8}$ cm., and $c=6.10 \times 10^{-8}$ cm. The lattice is occupied only at the corners, and there are 4 molecules Mg_2SiO_4 in each unit; it does not appear to be either an ortho- or a meta-silicate, but rather $4(\text{MgO.MgO.SiO}_2)$. The speed of crystallization at different temp. has been measured by E. Kittl. He found that the **speed of**

crystallization shows a sharp maximum at about 1370° , 20° above the temp. at which the crystallization of the glass begins; and he estimated that in the crystallization of the glass MgFeSiO_4 , there are 130,000 centres of crystallization per sq. cm.; with the glass $5\text{Mg}_2\text{SiO}_4 \cdot \text{Fe}_3\text{SiO}_4$, 430,000 centres; and with $9\text{Mg}_2\text{SiO}_4 \cdot \text{Fe}_2\text{SiO}_4$, 250 centres. The **cleavage** of olivine is distinct. Fig. 85 shows diagrammatically a transverse section of a prismatic crystal of olivine with obtuse angles 94° and acute angles 86° . The outer dotted line is the primary form. The broken lines are the rectangular cleavage. Most of those who have analyzed olivine also measured the **specific gravity**. In general, the sp. gr. rises with increasing iron content; thus:

Per cent. FeO	5.01	9.90	14.06	174.5	29.96	44.37
Sp. gr.	3.261	3.360	3.336	3.479	3.566	3.910

There are a few discrepancies dependent, in part, on the nature of the impurities associated with the olivine. The hardness is about 7. The m.p. varies markedly with the proportion of iron. The more ferruginous olivines are decomposed at a high temp., and the ferrous oxide is transformed into ferrous oxide. Hence, the m.p. determination loses its significance. V. Pöschl found for mixtures of forsterite and fayalite, *i.e.* of magnesium and ferrous orthosilicates,

Mg_2SiO_4	100	90	80	70	60 per cent.
Sp. gr.	3.11	3.16	3.30	3.36	3.46
M.p. mean	1600°	1350°	1332°	1322°	1350°

K. Thaddeeff, and A. Moitessier have studied the behaviour of olivine when heated in an oxidizing atm. The former found only three-fifths of the ferrous oxide was converted to ferric oxide. A. Brun's value for the m.p., *viz.* 1750° , is too high; C. Doelter found 1360° – 1410° , for a specimen from Kapfenstein; 1395° – 1430° for one from Söndmøre; 1310° – 1315° , for one from Somma; and 1395° – 1445° , for one from Egypt. A. des Cloizeaux gave for the **indices of refraction** $\alpha=1.661$, $\beta=1.678$, and $\gamma=1.697$. H. Backlund, M. Stark, N. H. Magnusson, and S. L. Penfield and E. H. Forbes investigated the relation between the proportion of contained iron and the optical properties. H. Backlund gave the results indicated in Table XVI. M. Stark found the **axial angle** decreases with increasing proportions of iron. S. C. Lind and D. C. Bardwell found no change of colour or thermoluminescence when peridot is exposed to **radium radiations**.

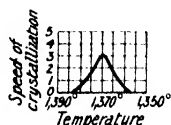

FIG. 84.—Effect of Temperature on the Speed of Crystallization of Olivine.

FIG. 85.—Transverse Section of Olivine.

TABLE XVI.—EFFECT OF THE PROPORTIONS OF IRON ON THE REFRACTIVE INDICES OF OLIVINE.

Occurrence.	Molar per cent. Fe_2SiO_4	α	β	γ	$\gamma-\alpha$
Ural	0.12	1.6361	1.6519	1.6698	0.0337

Limberg (hyalosiderite)	33.92	—	1.7276	1.7426	—
Hortonolite	67.45	1.7684	1.7915	1.8031	0.0347
Fayalite	98.40	1.8236	1.8642	1.8736	0.0500

F. von Kobell found that olivine is gelatinized when treated with sulphuric acid. Olivine is quite soluble in conc. hydrochloric acid, and the most ferruginous varieties dissolve fastest. The silicic acid which separates is granular. G. Tschermak said that it is meta- not ortho-silicic acid. V. Iskyul studied this subject. G. Lewinstein found that there is a 22.6 per cent. undissolved residue when olivine from Ihringen is treated with hydrochloric acid; and he analyzed the part which passed into soln. C. F. Rammelsberg made some observations on this subject. F. W. Clarke and E. A. Schneider treated olivine at 383°-412° with dry hydrogen chloride, and observed but a small proportion to be decomposed. G. A. Kenngott, and F. Cornu observed that powdered olivine has an alkaline reaction. R. Müller, E. W. Hoffmann, and A. Johnstone found that olivine is decomposed by carbonated water. H. Lotz studied the effect of air charged with sulphur dioxide on olivine. E. C. Sullivan studied the basic exchange which occurs with olivine in contact with soln. of cupric sulphate. V. Iskyul studied the solubility of silica in forsterite, olivine, and glauconite. Olivine readily weathers on exposure; serpentine and talc appear to be formed. The subject has been discussed by S. Hillebrand,⁷ G. Tschermak, P. V. von Jereméeff, B. Kolenko, W. Lindgren, J. F. Gmelin, K. A. Redlich, F. L. Hess, J. Roth, K. Busz, F. Becke, C. G. C. Bischof, A. E. Törnebohm, C. R. van Hise, A. M. Finlayson, etc. C. Madelung,⁸ J. R. Blum, and C. Doelter described the partial conversion of olivine into carbonate.

The mineral *villarsite* found by A. Dufrénoy⁹ at Traversella and named after M. Villars is a serpentinized olivine. It has also been described by L. R. Fellenberg, L. Heffter, L. Duparc and F. Pearce, A. Lacroix, A. des Cloizeaux, and W. T. Schaller. The so-called *iddingsite* is possibly a similar product.¹⁰ M. F. Heddle¹¹ described a mineral which he called *ferrite*. It was considered to be an olivine largely transformed into ferric oxide, etc. Similar products were described by A. Moitessier, F. Gonnard, K. Thaddéoff, and A. Liebrich. The *matricite* of N. O. Holst¹² found at Krangruba, Sweden, is a variety of olivine which has been weathered.

§ 28. Magnesium Metasilicates

Magnesium metasilicate introduces two classes of minerals—the pyroxenes and the amphiboles. The name **pyroxene** was originally applied by R. J. Haüy¹ to some greenish crystals which had been found in the lavas of Vesuvius, Etna, and Auvergne. He intended to indicate that the crystals were only accidentally caught up in the lavas which contained them—*πύρ*, fire; *ξένος*, a stranger—but in reality the pyroxenes come next to the feldspars in their abundant distribution in igneous rocks. Many different minerals have been called pyroxene, and the term is now used for a whole group of minerals which have a cleavage of about 88°, and which, excepting where they contain alumina, have the general metasilicate formula $M'SiO_3$. These minerals also pass into one another by a continuous series of solid soln. They include minerals belonging to three different systems.

The **rhombic pyroxenes** include *enstatite*, $MgSiO_3$; *bronzite* and *hypersthene*, $(Mg,Fe)SiO_3$. The **monoclinic pyroxenes** include *wollastonite*, $CaSiO_3$; *diopside*, $MgCa(SiO_3)_2$; *sahlite*, $(Mg,Fe)Ca(SiO_3)_2$; *hedenbergite*, $FeCa(SiO_3)_2$; *schefferite*, $(Mg,Fe)(Ca,Mn)(SiO_3)_2$; *jeffersonite*, $(Mg,Fe,Zn)(Ca,Mn)(SiO_3)_2$; *augite*, $(Mg,Fe)Ca(SiO_3)_2$; *jassauite*, $(Mg,Fe)(Al,Fe)_2SiO_6$; *spodumene*, $(Li,Na)Al(SiO_3)_2$; *acmite*, $NaFe(SiO_3)_2$; and

pectolite, $\text{Na}_2\text{Ca}_3(\text{SiO}_3)_3$. The **trielinic pyroxenes** include *rhodonite*, MnSiO_3 ; *bustamite*, $(\text{Mn,Ca})\text{SiO}_3$; *fowlerite*, $(\text{Mn,Fe,Ca,Zn})\text{SiO}_3$; *babingtonite*, $(\text{Ca}_2\text{Fe}''_2\text{Mn}_2\text{Fe}''_2)(\text{SiO}_3)_3$.

The term **amphibole**—from *ἀμφίβολος*, doubtful—was applied by R. J. Haüy to replace *schorl*, an old mining term previously applied to black tourmaline, hornblende, etc. The word is now used for a whole group of minerals related to the pyroxenes in being represented, except where alumina is present, by the general metasilicate formula $\text{M}'\text{SiO}_3$, and they likewise pass one into the other by a series of solid soln. The cleavage angle of the amphiboles is about 57° instead of 87° as with the pyroxenes. Like the pyroxenes, the amphiboles include minerals belonging to three different systems.

The **rhombic amphiboles** are rare. They include *anthophyllite*, $(\text{Mg,Fe})\text{SiO}_3$; and *gedrite*, $2(\text{Mg,Fe})\text{SiO}_3 \cdot \text{MgAl}_2\text{SiO}_5$. The **monoclinic amphiboles** are common. They include *cummingtonite*, $(\text{Fe,Mg})\text{SiO}_3$; *dannemorite*, $(\text{Fe,Mg,Mn})\text{SiO}_3$; *richterite*, $(\text{K},\text{Na}_2,\text{Mg,Ca,Mn})\text{SiO}_3$; *tremolite*, $\text{Mg}_2\text{Ca}(\text{SiO}_3)_4$; *actinolite*, $(\text{Mg,Fe})_2\text{Ca}(\text{SiO}_3)_4$; *hornblende*, $(\text{Mg,Fe})_2\text{Ca}(\text{SiO}_3)_4$; *edenite*, $\text{Na}_2\text{Al}_2(\text{SiO}_3)_4$; *pargasite*, $(\text{Mg,Fe})_2(\text{Al,Fe})(\text{SiO}_3)_4$; *arfvedsonite*, $(\text{Na}_2,\text{Ca,Fe})_2(\text{SiO}_3)_4$, and $(\text{Ca,Mg})_2(\text{Al,Fe})(\text{SiO}_3)_4$, and the related *barkervilleite*; *glaucoфанe*, $\text{NaAlSi}_3\text{O}_8$, or $(\text{Fe,Mg})\text{SiO}_3$; *riebeckite*, $\text{NaFeSi}_3\text{O}_8$; *jadeite*, $\text{NaAl}(\text{SiO}_3)_2$. **Trielinic amphibole** is rare, and is represented by *enigmatite*, $\text{Na}_4\text{Fe}_3(\text{Al,Fe})_2(\text{SiTi})_{11}\text{O}_{38}$.

According to E. T. Allen and co-workers,² **magnesium metasilicate**, MgSiO_3 , is tetramorphous. The different forms represent the end-members of four series of solid soln. represented by natural minerals. Two belong to the pyroxene family, and two to the amphibole family. Each of these families is represented by magnesium metasilicates which crystallize in the rhombic and monoclinic systems. They can be classed:

Magnesium metasilicates	{ Pyroxenic	{ rhombic . . .	Enstatite
		{ monoclinic . . .	Clinoenstatite
	{ Amphibolic	{ rhombic . . .	Anthophyllite
		{ monoclinic . . .	Clinoanthophyllite

A fifth rhombic form, called *α-magnesium metasilicate*, was reported by E. T. Allen and co-workers to be an enantiomorphic variety of ordinary clinoenstatite, which they called *β-magnesium metasilicate*. The transition temp. was given as 1365° . N. L. Bowen and O. Andersen, however, showed that the alleged *α-MgSiO₃* is really a product of the dissociation of clinoenstatite at 1557° , being therefore magnesium orthosilicate, *i.e.* forsterite, and not a form of the metasilicate: $2\text{MgSiO}_3 \rightleftharpoons \text{Mg}_2\text{SiO}_4 + \text{SiO}_2$. On account of the breaking up of clinoenstatite into forsterite and liquid, there is no eutectic between these two compounds, Fig. 100; but, on cooling the liquids, there is a complete or partial re-solution of forsterite at 1557° , and clinoenstatite is formed.

Native magnesium metasilicate free from iron is scarce. The name **enstatite** was applied by G. A. Kenngott to a white, yellowish, greyish, or greenish white mineral which he found in the Zdjár Mt., Moravia, and which had been previously regarded as seapolite. The term *enstatite*—*ἐνστάτης*, an opponent—was intended to refer to its refractoriness. He noted the close chemical relationship between it and the rhombic pyroxenes: *bronzite*, and *hypersthene*. The dark brown, or greyish, or greenish-black mineral designated *labradorische Hornblende* by A. G. Werner, and L. A. Emmerling, was recognized by R. J. Haüy, in 1803, to be different from hornblende, and he accordingly renamed it **hypersthene**, from *ὑπέρ*, very; *σθένος*, strong, in reference to its exceeding hornblende in hardness or toughness. He had previously called the mineral *diabase métalloïde*. A. G. Werner named the hypersthene from Paul Island, Labrador, *paulite*. The term **bronzite** was used by D. L. G. Karsten and M. H. Klaproth for a mineral with a bronze metallic lustre obtained from Styria. R. J. Haüy referred to it as being *une variété fibro-laminaire métalloïde à reflets bronzés*. A. Breithaupt, F. Mohs, E. F. Glockner, W. Haidinger, J. F. Hausmann, C. Hartmann, etc., referred *paulite* and *bronzite* to the same mineral species.

About 1869, G. vom Rath described crystals of a rhombic pyroxene which he obtained from the volcanic ejecta at Lake Laach, and which he called *amblystegite*— $\alpha\mu\beta\lambda\upsilon\varsigma$, blunt; $\alpha\tau\epsilon\lambda\gamma\gamma$, dome, in reference to the form of the crystals. He later identified this with hypersthene. S. Meunier called the enstatite from a meteorite at Deesa, Chile, *vicitorite*, in honour of Victor Meunier. C. U. Shepard described crystals of what he regarded as magnesium trisilicate, and named *chladnite*, which he found in a meteorite at Bishopville, South Carolina. The observations of G. S. von Waltershausen, J. L. Smith, C. F. Rammelsberg, and G. A. Kenngott showed that chladnite is essentially enstatite. G. Rose called the mineral *shepardite*, but this term had been previously applied to another mineral by W. Haidinger in 1847. G. Tschermak separated from the same mineral a ferruginous pyroxene, like bronzite, which he named *diogenite*, after Diogenes of Apollonia. The *azaboste* of A. Koch, and A. von Lasaulx was shown by J. A. Krenner, and F. Koch to be hypersthene. The *schiller-spar* of Baste in the Harz, etc., was described by M. F. Heddle, F. W. H. von Trebra, C. Heyer, F. Köhler, J. F. Gmelin, J. C. Freisleben, W. Hetzer, F. Pisani, D. L. G. Karsten, L. A. Emmerling, B. J. Haiiy, A. J. M. Brochant, J. F. Hausmann, G. A. Kenngott, K. Johansson, A. Breithaupt, A. G. Werner, F. Mohs, etc. W. Haidinger called it *basite*. G. Rose showed that schiller-spar is probably an alteration product of a mineral of the pyroxene group. This was confirmed by F. Köhler, J. A. Drappier, H. Girard, A. Baentsch, and A. Streng. The fresh mineral was called *protobastite* and regarded as being allied to bronzite. M. Websky, G. Tschermak, and H. Rosenbusch showed that there are no real reasons for regarding protobastite and enstatite as distinct mineral species. A. Breithaupt applied the term *phastine* to an alteration product of bronzite or a bronzo-like pyroxene. A similar view was taken by A. des Cloizeaux, G. Tschermak, and K. von Drasche. A yellow pyroxene with a mother-of-pearl lustre, obtained by A. Breithaupt from the serpentine at Matry, Tyrol, etc., was called *diacase*—or, according to J. F. Hausmann, *diacaseite*— $\delta\iota\alpha$, through; $\kappa\lambda\alpha\sigma\tau\acute{o}\varsigma$, broken. A. G. Werner called it *schillerstein*; J. C. Freisleben, yellow schiller-spar; R. J. Haiiy, *diallage verte*; and J. P. Hausmann, pale-like hornblende. F. Köhler, A. Streng, C. F. Rammelsberg, A. des Cloizeaux, M. Websky, etc., made some observations on the mineral and co-ordinated it with enstatite or hypersthene. The *germarite* of A. Breithaupt is a slightly altered hypersthene. J. L. Smith applied the term *peckhamite*, after S. F. Peckham, to some rounded nodules he found in the meteorite of Estherville, Iowa. It is not clear if this is a mixture of enstatite and, say, olivine. G. Tschermak gave the name *grammitite* to the mixture, presumably, of plagioclase, enstatite, and olivine, which occurred in a meteorite from Sierra de Chaco; and S. Meunier, *logronite* to that in a meteorite at Barea, Logrono, Spain. C. U. Shepard found what appeared to be a hydrated bronzite which he called *amillite*. Its composition approached that of serpentine.

C. Hintze has given a list of the many places where enstatite, bronzite, and hypersthene have been reported, and they include nearly all countries on earth—in England and Scotland,² Germany,⁴ Hungary,⁵ Austria,⁶ Italy,⁷ Portugal,⁸ Spain,⁹ France,¹⁰ Santorin,¹¹ Norway,¹² Sweden,¹³ Finland,¹⁴ Urals,¹⁵ Siberia,¹⁶ Russia,¹⁷ Cracow,¹⁸ Persia,¹⁹ Sumatra and Borneo,²⁰ Japan,²¹ South America,²² United States,²³ Canada,²⁴ Labrador,²⁵ Greenland,²⁶ Africa,²⁷ and New Zealand.²⁸ The occurrence of enstatite, bronzite, or hypersthene in meteorites has been investigated by C. U. Shepard,²⁹ N. S. Maskelyne, G. Tschermak, etc.

Analyses are given by most of the authorities quoted in connection with the occurrence of the mineral. The magnesia content of enstatite varies from 29.7–41.8 per cent.; the silica from 54.0–62.1 per cent.; the ferrous oxide from 0.21–4.5 per cent.; the alumina from mere traces up to about 3 per cent. A little alkali, manganese oxide, nickel oxide, chromic oxide, sulphate, phosphate, carbonate, and water may also be present. In bronzites and hypersthene, the magnesia ranges from about 15–36 per cent.; the silica from about 50–58 per cent.; the ferrous oxide from 5–25 per cent.; the alumina from mere traces to about 5 per cent., although there are a few with alumina ranging up to that of the aluminous pyroxenes, say, 10 per cent. Eliminating what are thought to be accidental contaminations, there appears to be a continuous series of solid soln., with magnesium metasilicate and ferrous metasilicate as terminal members. The term enstatite is applied to the forms near the magnesium silicate end of the series. There is no sharp line of demarcation between enstatite and hypersthene. Bronzite is usually considered to be intermediate between enstatite and hypersthene; but, the affixing of a lower limit for the proportion of ferrous oxide for bronzite and hypersthene is quite an arbitrary convention. The general formula may therefore be written $(\text{Mg}, \text{Fe})\text{SiO}_3$; and in the tables of analyses, the ratio Mg : Fe in enstatite, and bronzite ranges from 8 : 1 to about 3 : 1; while in hypersthene, this ratio falls from 3 : 1 to nearly 1 : 1. Some-

what similar suggestions were made by A. des Cloizeaux,³⁰ G. A. Kenngott, G. Tschermak, etc. C. Hintze considers the two minerals enstatite and hypersthene, and applies the term bronzite only to those varieties showing schillerization.

E. T. Allen, F. E. Wright, and J. K. Clement³¹ prepared rhombic enstatite, or magnesium metasilicate free from iron oxide, by suddenly quenching the thoroughly molten metasilicate glass in water; and afterwards annealing the glass in fragments of about 10 grms. between 1000° and 1100°. The crystallization begins at the surface and proceeds inwards with a rise of temp. The outer portion contracts, and squeezes out the liquid interior, forming hollow, rounded projections which crystallize last. If the temp. be 1125° or higher, the rhombic enstatite is accompanied by the monoclinic form, and this the more the higher the temp.; over 1300°, nearly all the product is monoclinic. M. Schmidt claimed that when the glass is rapidly cooled the monoclinic form predominates, and if slowly cooled a smaller proportion is formed. E. T. Allen and co-workers also point out that the alleged syntheses of enstatite by J. J. Ebelmen, P. Hautefeuille, and S. Meunier were afterwards shown by F. Fouqué and A. Michel-Lévy, and J. H. L. Vogt, to be really clinoenstatite. A. Daubrée melted portions of meteorites, but obtained crystals too opaque to determine their optical properties—monoclinic or rhombic. He also melted a mixture of olivine and 15 per cent. of silica, and obtained a fibrous mass with the properties of enstatite. E. T. Allen and co-workers, however, found that clinoenstatite is formed under these conditions. F. Fouqué and A. Michel-Lévy prepared rhombic enstatite, mixed with but a small amount of the monoclinic form, by melting and rapidly cooling a mixture of 12 grms. of silica, 3 grms. of magnesia, and 5 grms. of ferric oxide. The cold cake contained arborescent crystals which developed into needles with parallel extinction when reheated at a temp. just over the m.p. of copper. J. Morozewicz obtained rhombic enstatite in his experiments on the synthesis of basalt. J. H. L. Vogt, and W. Wahl suggested that the production of the monoclinic form is favoured by the presence of ferrous oxide, and calcium oxide.

The colour of the crystals is largely determined by the contained iron and varies from a brownish-green, olive-green, greenish-brown, or black, or greenish, greyish, or yellowish white. The lustre may be glassy, mother-of-pearl, or metallic. The enstatite prepared by E. T. Allen and co-workers was obtained only in fibrous aggregates and radial spherulites which did not admit of the measurement of the morphologic constants. The direction of elongation of the fibres in the spherules was not that of the prism axis, but parallel to that of the greater ellipsoidal axis. The crystals of the minerals enstatite, bronzite, and hypersthene have been measured by C. F. Rammelsberg, B. Weigand, F. Becke, H. Bücking, H. Sommerlad, A. des Cloizeaux, A. Schmidt, J. A. Krenner, G. H. Williams, W. C. Brögger and H. H. Reusch, H. Rosenbusch, Y. Kikuchi, N. V. Ussing, V. von Lang, etc. According to G. vom Rath, the rhombic crystals have the axial ratios $a:b:c = 0.97133:1:0.57000$. E. T. Allen and co-workers found the cleavage of artificial enstatite to be well marked, making an angle approximately 90°. The optic axial angle ranged from 44°–70°. G. Tschermak found the axial angle depends on the proportion of contained iron. Thus, for yellow light (and for red light in the case of those marked *):

Per cent. FeO	2.76	5.77	9.86	15.14	19.70	27.70	33.60
Axial angle	*133° 8'	*123° 38'	106° 51'	98° 0'	84° 18'	79° 48'	59° 20'

According to A. des Cloizeaux, raising the temp. to about 75° produced no perceptible change in the angles of the optic axes. C. Berndt studied the X-radiogram of olivine. E. Kittl found sharp maxima in the variation of the speed of crystallization of bronzite and hypersthene with temp. as illustrated in Figs. 86 and 87. He estimated that during crystallization with magnesium metasilicate there are 930 centres of crystallization per sq. cm.; with bronzite, 14 per sq. cm.

The specific gravity of artificial enstatite, free from the monoclinic variety, was

found by E. T. Allen and co-workers to be 3.175 at 25°. The sp. gr. of many of the specimens of enstatite and bronzite, indicated above, were determined, and, as a rule, the sp. gr. has a tendency to rise as the proportion of the contained iron increases:

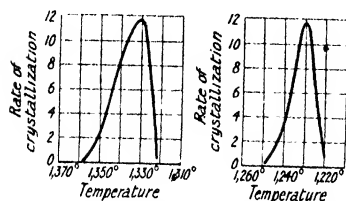

Per cent. FeO	0.90	6.44	13.6	19.84	26.93
Sp. gr.	3.217	3.308	3.333	3.487	3.531

There are, however, many apparent exceptions due to the presence of impurities, differences in the method of determination, etc. The **hardness** ranges from 5-6.

L. H. Adams and E. D. Williamson found the **compressibility** of enstatite, $(\text{MgSiO}_3)_{88}(\text{FeSiO}_3)_{12}$, to be $\beta = 1.03 \times 10^{-6}$ between 0 and 10,000 megabars press.; and for hypersthene, $(\text{MgSiO}_3)_{70}(\text{FeSiO}_3)_{30}$, $\beta = 1.01 \times 10^{-6}$ between 0 and 10,000 megabars press. J. Joly gave 0.179 for the **specific heat** of hypersthene between 13.3° and 100°; and R. Ullrich, 0.1914 between 19° and 98°. W. P. White gave for the mean **atomic heat** of magnesium metasilicate, MgSiO_3 , 4.42 at 100°; 5.26 at 300°; 5.62 at 500°; 5.87 at 700°; and 6.04 at 900°. E. T. Allen and co-workers gave 1521° for the **melting point** of artificial enstatite. C. Doelter gave 1380°-1400° for the m.p. of enstatite; and 1330°-1380° for bronzite; J. Joly gave for bronzite, 1300°; R. Cusack, 1295°; and A. L. Fletcher, 1345°. V. S. Deleano gave 1500° for the m.p. of enstatite; and Y. Yamashita and M. Majima gave 1459° for the m.p. of bronzite. According to N. L. Bowen and O. Andersen, magnesium metasilicate has no true m.p. where solid MgSiO_3 is in equilibrium with a liquid of its own composition. There is a strong absorption of heat at 1557°, but this is not the m.p., for at that temp. the metasilicate dissociates into the orthosilicate and liquid; and the dissolution of the forsterite is completed only by raising the temp. to about 1577°—vide Fig. 98. R. Lorenz and W. Herz studied the relation between the m.p. and the transition temp.; and V. S. Deleano, the softening temp. of mixtures of magnesium ortho- and meta-silicates, and found:

Per cent. Mg_2SiO_4	80	60	40	30	20	10	0
Softening temp.	1640°	1605°	1520°	1480°	1500°	1505°	1500°

E. T. Allen and co-workers found the **indices of refraction** of artificial enstatite to be $\alpha = 1.640$, $\beta = 1.646$, and $\gamma = 1.652$, each ± 0.004 . The birefringence is not strong, about 0.01. The optical character of enstatite is positive, that of hypersthene, negative. The **extinction** of enstatite is parallel, while that of the monoclinic variety is oblique. E. Mallard gave for the mineral from Zdjár Mt., Moravia, with 2.76 per cent. FeO, $\alpha = 1.656$, $\beta = 1.659$, and $\gamma = 1.665$; and A. Michel-Lévy and A. Lacroix, for a sample from Paul Island, Labrador, with about 22.6 per cent. of iron, $\alpha = 1.692$, $\beta = 1.702$, and $\gamma = 1.705$. W. W. Coblentz found the ultra-red transmission spectrum gave a large absorption band at 1.85μ , and smaller depressions at 2.9μ and 5.2μ . The reflection spectrum shows a small maximum at 9.1μ . The **pleochroism** is dependent upon the proportion of contained iron; it is scarcely perceptible in samples free from iron. G. Tschermak found that with a sample from Paul Island, with about 22.6 per cent. of FeO, α is hyacinth-red; β , reddish-yellow; and γ , greyish-green; F. Becke gave for a sample from Bodenmais, Bavaria, with 18.6 per cent. FeO, α , dark reddish-brown; β , yellowish-brown; and γ , dark green; while G. Tschermak gave for a sample from Kraubat, Styria, α , greenish-yellow; β , grass-green; and γ , bluish-green. H. Rosenbusch also dis-

FIGS. 86 and 87.—Effect of Temperature on the Speed of Crystallization of Bronzite and Hypersthene.

cussed this subject. The **schillerization** of the surface has been described by B. Kosmann, P. Trippke, H. Rosenbusch, and J. W. Judd. The *schiller* is an interference effect generally attributed to the presence of very thin films or scales of oxides or hydroxides of iron in the cleavage cracks—*vide feldspar*.

Hydrochloric acid has but little action on enstatite, but the effect becomes more and more marked as the proportion of iron increases. N. S. Maskelyne found that after an hour's digestion of a sample of enstatite from Bustee with $\text{HCl} + \text{H}_2\text{O}$, the liquid had 7.78 per cent. of matter in soln.; 20 hrs.' digestion of two other varieties gave 9.41 and 12.68 per cent.—in the latter case, the sample was more ferruginous than in the former case. E. Cohen found that by 48 hrs.' digestion with fuming hydrochloric acid, 13 per cent. passed into soln. C. Doelter passed hydrogen chloride over red-hot enstatite and anthophyllite, and only in the latter case was matter produced which was soluble in water. C. Doelter digested enstatite and a 10 per cent. soln. of sodium hydroxide in a sealed tube at 180° for 9 weeks, but no appreciable solvent action was observed; with 12 hrs.' digestion in a 12 per cent. soln. of potassium hydroxide, 4.84 per cent. was dissolved. The silica content of the residue decreased, while the manganese content remained unchanged, and the water content was raised about 4 per cent. By digesting artificial enstatite in 2.5N-NaOH, about 4 per cent. passed into soln. in 4 hrs. E. C. Sullivan studied the basic exchange which occurs with olivine in contact with a soln. of cupric sulphate. C. R. van Hise discussed the transformation of bronzite and hypersthene into talc by the action of water, or carbonic acid. C. Simmonds found hypersthene to be only partially reduced by hydrogen at a red heat.

As indicated above, the early syntheses of enstatite really produced monoclinic, not rhombic, crystals. J. J. Ebelmen fused a mixture of silica, magnesia, and boric oxide. A. Daubrée fused meteorites; magnesian eruptive rocks; mixtures of olivine and silica; and serpentine. W. Pukall obtained what was probably clinoenstatite by heating the right proportions of magnesia and silicic acid in a silver crucible. P. Hautefeuille dissolved amorphous silica in molten magnesium chloride. S. Meunier acted on magnesium vap. with silicon chloride and steam. F. Fouqué and A. Michel-Lévy, J. H. L. Vogt, and E. T. Allen and co-workers found that in all these cases the main product is monoclinic pyroxenic enstatite; or, using the term suggested by W. Wahl, **clinoenstatite**. H. Michel detected clinoenstatite in meteorites. G. Zinko made it by fusing mixtures of magnesium and ferrous metasilicates. He found that bismuth oxide, magnesium fluoride or chloride, or calcium fluoride had no effect as *agent minéralisateur*. E. T. Allen and co-workers found that clinoenstatite is the most stable form of magnesium metasilicate. It is formed when the metasilicate glass is allowed to crystallize at a little below 1521° ; and that it can be crystallized at lower temp. from soln. in molten sodium vanadate, magnesium vanadate, or magnesium tellurite. The three other forms of magnesium metasilicate pass into this variety when they are heated in molten magnesium chloride to about 1000° , and in a stream of dry hydrogen chloride. N. L. Bowen and O. Andersen studied the synthesis of clinoenstatite.

The **crystals** of clinoenstatite obtained by these different processes are usually small; those obtained from the glass appear as large spherulitic masses of radiating fibres. E. T. Allen and co-workers found that monoclinic crystals have the axial ratios $a:b:c=1.033:1:0.77$ when those of rhombic crystals are $1.0308:1:0.5885$. F. Zambonini said that the crystals of clinoenstatite are identical with those of enstatite having the axial ratios $a:b:c=1.0331:1:0.591$ and $\beta=90^\circ 49'$; but F. E. Wright does not agree. There is almost always polysynthetic **twinning** after the orthopinacoid; and it is very characteristic. Between crossed nicols, the sections frequently very closely resemble those of plagioclase. The **cleavage** is prismatic like that of the pyroxenes. The plane of the **optic axes** is normal to the (010)-face, and in the plane of the clinopinacoid. The **optic axial angle** is large; F. E. Wright and E. S. Larsen found 53.5° . The **specific gravity** at $25^\circ/25^\circ$ is 3.192. The m.p. is indicated in connection with enstatite. E. T. Allen and

co-workers give 6 for the **hardness**; and for the **indices of refraction**, $\alpha=1.64$, $\beta=1.652$, and $\gamma=1.658$, each ± 0.003 ; N. L. Bowen and O. Andersen gave $\alpha=1.65$ and $\beta=1.660$, each ± 0.001 . The **birefringence** is about 0.01. The **extinction angle** on the clinopinacoid is very low for a pyroxene, and for crystals with poly synthetic twinning—as is the case with feldspars—the extinction angle $19.5^\circ-24.5^\circ$ was obtained by using the symmetrical extinction angles of adjacent lamellae. The crystals are only slightly attacked by acids. W. Pukall observed that no hydrate is formed when the metasilicate lies under water for some time. V. Iskyul studied the action of hydrochloric acid on enstatite, and bronzite.

J. A. Michaelson³² obtained a yellowish or reddish-brown, augite-like mineral from Långban and Pejsberg, Sweden. It was called *schefferite*—after H. T. Scheffer—and described by A. Breithaupt as *wallerian*. It contained 50.88–52.28 per cent. SiO_2 ; 3.83–17.48 per cent. FeO ; 9.08–15.17 per cent. MgO ; 12.72–19.62 per cent. CaO ; and 6.67–8.32 per cent. MnO . It is a monoclinic pyroxene, and probably a complex solid soln., not a chemical individual. A dark variety rich in iron was called *eisenschefferite* by G. Flink, who represented his analyses by the formula $6\text{CaMg}(\text{SiO}_3)_2 \cdot \text{MgFe}(\text{SiO}_3)_2 \cdot 2\text{MnSiO}_3$. C. Doelter synthesized schefferite by crystallization from the molten constituents. Schefferite is then regarded as a mixed monoclinic pyroxene. The optic axial angles were measured by G. Flink, and by J. Sioma. The latter gave for the sp. gr. $3.457-3.546$. C. Doelter gave $1200^\circ-1250^\circ$ for the m.p.; $\alpha=1.660$, and $\gamma=1.698$ for the indices of refraction; and for the birefringence, $\gamma-\alpha=0.035$.

V. Schumacher³³ discovered a mineral which occurred near Kongsberg, Norway, in thin long plates, and fibres, and which he named **anthophyllite**—from *anthophyllum*, clove—in allusion to its clove-brown colour. The name was abbreviated to *anthophyllite* by D. L. G. Karsten. A. G. Werner referred to a *strahligen* anthophyllite and a *blättrigen* anthophyllite, the latter was bronzite, and A. Breithaupt called the former *antholite*, and later *anthogrammite*. J. F. John made analyses of the mineral, and J. F. Gmelin showed by analysis that anthophyllite is a ferruginous magnesium silicate; and A. des Cloizeaux, that its optical properties belong to a member of the rhombic system. K. C. Sullivan studied the basic exchange with anthophyllite in contact with soln. of cupric sulphate.

N. von Kokscharoff described a magnesian silicate from the Senarka River, Ural; and it was also obtained from the Tunkinsk Mt. near Lake Baikal. R. Hermann reported a specimen from Minsk in the Ilmen Mts. It was named *kupferite* after A. T. Kupffer. N. von Kokscharoff said the kupferite occurs in rhombic prisms, and, according to C. Hintze, this, through a misunderstanding, was taken to mean that it belonged to the rhombic system. Thus, G. A. Kenngott, and E. S. Dana regarded it as the amphibole analogue of enstatite. It was examined by J. Löfven. E. T. Allen and J. K. Clement found that water is always present, not combined, but dissolved, as in tremolite. A. des Cloizeaux referred to an amphibole of the same chemical composition as anthophyllite as *amphibolic-anthophyllite*. A. Dufrénoy obtained a dark-coloured mineral analogous to anthophyllite from the valley of Héas near Gêdres, France, and he called it *gedrite*. A. des Cloizeaux showed that the optical properties of gedrite and anthophyllite are analogous. A. Breithaupt's *thalackerite* is an anthophyllite from Greenland with a metallic lustre; and A. Breithaupt, and F. Pisani's *enarumite* is an altered anthophyllite. Several hydrated and altered anthophyllites have been described by T. Thomson, J. L. Smith and G. J. Brush, A. Lacroix, and M. F. Heddle. The *piddingtonite* of W. Haidinger was found in the meteorite first described by H. Piddington, and is very close to anthophyllite in composition.

Anthophyllite occurring in England and Scotland has been described by J. J. H. Teall, M. F. Heddle, and A. Lacroix; in Germany, by W. Beck, G. A. Kenngott, C. W. von Gümbel, C. F. Rammelsberg, A. Frenzel, and F. Becke; in France, by A. P. Dufrénoy, A. Lacroix, W. Cross, C. Friedel, F. Gonnard, and F. Pisani; in Norway, by T. Scheerer, J. F. Gmelin, F. Pisani, L. Vopelius, C. C. von Leonhard, A. des Cloizeaux, H. Sjögren, and A. Breithaupt; in Finland, by F. J. Wik; in Austria, by J. Ippen, F. Becke, and H. Commenda; in Moravia, by G. Tschermak, A. Brezina, W. C. Bladsale, and V. von Zepharovich; in North America, by S. L. Penfield, J. R. Blum, J. Pratt, B. K. Emerson, T. Thomsen, N. N. Evans and J. A. Bancroft, and A. des Cloizeaux; in Greenland, by O. Bøggild, A. des Cloizeaux, H. Rose, M. Lappe, and N. V. Ussing; and in the Urals, by G. Rose.

Analyses have been made by many of the observers mentioned in connection with the occurrence of the mineral. E. T. Allen and J. K. Clement found kupferite

(rhombic) containing nearly 4 per cent. of water which is slowly and continuously lost by heating the mineral to about 900°. The water is assumed not to be chemically combined, but adsorbed or in solid soln. Eliminating what are considered to be accidental impurities, the idealized mineral appears to be rhombic magnesium metasilicate of the amphibole type; and the actual mineral, solid soln. of magnesium and ferrous metasilicates. The formula thus reduces to $(\text{Mg,Fe})\text{SiO}_3$, where the ratio $\text{Mg} : \text{Fe}$ ranges from 2 : 1 to 8 : 1. The relation between gedrite and anthophyllite may be likened to that between hypersthene and enstatite. In some cases, the gedrites carry up to about 16 per cent. of alumina, and the mineral becomes an aluminous amphibole, or it is present as an aluminosilicate, $\text{MgAl}_2\text{SiO}_8$. B. Gossner represented anthophyllite by $[\text{2SiO}_2.\text{Mg}(\text{OH})_2].6\text{MgSiO}_3$; and gedrite, by $[\text{SiO}_2.2\text{AlO}(\text{OH})].6\text{MgSiO}_3$. E. T. Allen and co-workers made rhombic amphibolic magnesium metasilicate, *i.e.* the end-term of the series of solid soln. or idealized anthophyllite, by rapidly cooling the molten magnesium silicate glass from a temp. over 1500°; and then annealing the product between say 1177° and 1180°. The crystallization usually begins on the upper surface of the melt near the walls of the crucible, forming a fringe of converging fibres which grow towards the centre of the mass. The amphibolic form readily passes into monoclinic pyroxene with the evolution of heat.

The **colour** of anthophyllite ranges through brownish-grey, yellowish-brown, brownish-green, emerald-green, and almost black. The artificial form is white and porcelainic. Anthophyllite sometimes shows a pearly lustre on the cleavage faces. It often occurs in lamellar or fibrous masses. **Crystals** are rare; but they have the prismatic habit, and may occur in aggregates of prisms. The crystals belong to the rhombic system, and, according to S. L. Penfield, they have the axial ratios $a : b : c = 0.5137 : 1 : ?$ with the prism angle $125^\circ 27'$, while for an aluminous gedrite, N. V. Ussing gave for the axial ratios $a : b : c = 0.5229 : 1 : ?$ with a prism angle of $124^\circ 48'$. E. T. Allen and co-workers obtained for the magnesium metasilicate analogue, radical spherulites and fibrous aggregates, but crystals suitable for the measurement of the morphologic constants were not obtained. The **cleavage** of anthophyllite is prismatic and perfect; and E. T. Allen and co-workers observed an indistinct cleavage at an angle of 120° . The plane of the optic axes lies parallel to the long direction; the **optic axial angle** is large. A. des Cloizeaux, and A. Michel-Lévy and A. Lacroix measured the axial angles of anthophyllite, and found for $2H$, for red light, $110^\circ 49'$ to $112^\circ 13\frac{1}{2}'$, and, for blue light, $109^\circ 5'$ to $111^\circ 5\frac{1}{2}'$; for red light $2V$ is $95^\circ 8'$ to $96^\circ 12'$, and, for blue light, $94^\circ 14'$ to $95^\circ 46'$. S. L. Penfield gave $90^\circ 4'$ for $2V$ for Li-light, $88^\circ 46'$ for Na-light, and $87^\circ 28'$ for Tl-light. N. V. Ussing gave for a sample of gedrite $2V = 78^\circ 33'$, and $2H$, $89^\circ 24'$ for red light, $89^\circ 6'$ for yellow light, and $88^\circ 45'$ for green light; N. L. Bowen gave $2V = 88^\circ 46'$. The axial angle decreases with increasing iron and alumina content. A. des Cloizeaux observed no perceptible change in the axial angles by raising the temp. to 146.5° . H. Mark discussed the structure of the crystals.

The **specific gravity** of the preparation of E. T. Allen and co-workers was 2.857 at 25° . S. L. Penfield gave 3.093 for the sp. gr. of anthophyllite with 10.39 per cent. FeO. F. Pisani, 2.98 (12.40 per cent. FeO); M. F. Heddle, 3.068 (8.13 per cent. FeO); A. Dufrénoy, 3.260 (45.83 per cent. FeO); F. Gonnard, 2.9-3.0; A. des Cloizeaux, 3.225 (28.9 per cent. FeO), etc. The **hardness** is 5.5-6.0. A. Brun gave 1150° - 1230° for the **melting point** of anthophyllite; and C. Doelter, 1325° - 1340° . E. T. Allen and co-workers observed that the rhombic amphibolic type changes into clinoenstatite when heated to a sufficiently high temp. A similar result was obtained with enstatite. The change is sluggish. There were indications of the change in a sample heated for 2 days between 1055° and 1077° ; but no change was observed in 20 hrs. at 1100° ; the change was observed after 18 hrs. heating between 1120° - 1140° ; and all was changed after 3 days' heating between 1127° - 1153° .

The **indices of refraction** of anthophyllite were measured by A. des Cloizeaux. A. Michel-Lévy and A. Lacroix found $\alpha=1.633$, $\beta=1.642$, $\gamma=1.657$; and N. V. Ussing found for red light with gedrite, $\alpha=1.623$, $\beta=1.6358$, and $\gamma=1.6439$. S. L. Penfield gave for anthophyllite $\beta=1.6276$ with Li-light; $\beta=1.6353$ with Na-light; and $\beta=1.6495$ with Tl-light. N. L. Bowen gave $\alpha=1.6195$, $\beta=1.6301$, and $\gamma=1.6404$. E. T. Allen and co-workers found for their amphibolic magnesium metasilicate, $\alpha=1.591$, and $\beta=1.578$, each ± 0.004 . The **birefringence** is approximately 0.013, and the **interference colours** are confined to the bright tints of the first and second orders. The **extinction** is usually parallel to the direction of elongation, though in a few cases a small angle of 3° – 6° was observed, indicating intergrowths of rhombic and monoclinic amphiboles. The optical character is positive—anthophyllite was found by A. des Cloizeaux to be optically positive for red, negative for yellow and green light; while gedrite was found by N. V. Ussing to be optically negative. H. Rosenbusch found the **pleochroism** depends on the depth of colour. In the γ -direction the colour is pale yellowish-brown, greenish, or colourless, and in the α and β directions clove-brown.

Anthophyllite is not decomposed by acids. C. Doelter found that when powdered anthophyllite is exposed for 3 hrs. at a red heat to dry hydrogen chloride, about 3 per cent. becomes soluble. When treated with 2 per cent. hydrofluoric acid, about 46.23 per cent. passed into soln. V. Iskyul studied the action of hydrochloric acid, and the solubility of silica in enstatite, bronzite, and anthophyllite; he found the silica solubility of the amphiboles is twice as great as that of the pyroxenes. C. R. van Hise discussed the transformation of anthophyllite into talc by the action of water.

E. T. Allen and co-workers frequently found small quantities of the monoclinic amphibolic form of magnesium metasilicate, **clinoanthophyllite**, when the glass is more or less rapidly cooled; and when water is allowed to act on the rhombic form at 375° – 475° , the monoclinic form appears more abundantly. Well-formed crystals were not obtained. K. Chrustschoff reported the synthesis of an amphibole by heating a mixture of silicic acid, alumina, lime, magnesia, alkalies, ferrous and ferric oxides, and water in a glass vessel for 3 mons. at 550° . The kind of glass is not stated. As indicated above, N. von Kokscharoff described the crystals of kufferite as being monoclinic. E. T. Allen found that the maximum extinction angle is 11° , though more usually the angle is smaller, 4° – 8° . The average refractive index is nearly the same as that of rhombic anthophyllite, and the birefringences are the same order of magnitude.

There are cases of allotropy in which two or more solids yield identical liquids, soln., and vap. When one form passes without melting into another form at a definite temp.—called the **inversion point**, or the **transition temperature**—and the change is reversible, the substances are said to be enantiotropic allotropes—*enantiotropos*, opposite; *ἑνάντιος*, habit. For example, the α - and β -forms of sulphur; wollastonite and pseudowollastonite, etc. In this case, J. H. van't Hoff showed that the inversion of the form stable at the lower temp. to the second form is attended by an absorption of heat, and the reverse change occurs with an evolution of heat. The vap. press. relations are illustrated diagrammatically in Fig. 88, where T_2 represents the inversion temp., and T_1 the m.p.; aT_1b represents the vap. press. of the liquid; dT_2 , the vap. press. of the solid stable below T_2 ; and T_2T_1 , the vap. press. of the solid stable above T_2 . The dotted lines represent metastable states. Under ordinary conditions, the line aT_2 does not intersect aT_1b , the solid stable at the lower temp. has no m.p. In another case of allotropy, when there is no such inversion temp., the change is irreversible, and one form is metastable at all temp. below the m.p., the substances are said to be monotropic allotropes, e.g. diamond and graphite, explosive antimony, etc. The vap. press. relations are illustrated diagrammatically by Fig. 89, where T_1 represents the m.p. of the stable form; T_2 , the m.p. of the unstable form; aT_2T_1b is the vap. press. curve of the liquid; cT_2 , the vap. press. curve of the unstable solid; and dT_1 , the vap. press.

curve of the stable solid. For a given temp., the vap. press. of the unstable form is always greater than that of the stable form; the two curves do not intersect below the m.p. of either form, and the two solids are not therefore in equilibrium at any temp. The solid with the lower vap. press. is the more stable form at all temp. The m.p. of the unstable form is therefore lower than that of the stable form. In practice the unstable form changes into the stable form before its own m.p. is reached. The tetramorphic forms of magnesium metasilicates are examples of monotropism. The case is illustrated diagrammatically by Fig. 90, where clinoenstatite is the stable form. In view of Figs. 88 and 89, Fig. 90 explains itself.

§ 29. The Higher Silicates of Magnesium

The *melilite group of minerals* (q.v.) belonging to the tetragonal system includes a series of aluminosilicates—melilite, a complex aluminosilicate; gehlenite, $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$; sarcolite, $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2$; and velardinite, $2\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{SiO}_2$. J. H. L. Vogt¹ assumed that the idealized type is *akermanite* named after R. Akerman—which he represented by $4\text{CaO} \cdot 3\text{SiO}_2$. The calcium oxide is in part replaced by magnesia or the oxides of manganese and iron. The mineral is formed during the rapid cooling of certain slags. A. L. Day and E. S. Shepherd were unable to obtain any evidence of the formation of J. H. L. Vogt's akermanite on the f.p. curves of fused mixtures of lime and silica—Fig. 70. There is, therefore, no evidence of the existence of this compound other than J. H. L. Vogt's analysis of the crystals in the slags which ran: SiO_2 , 43.17 per cent.; Al_2O_3 , 3.43; MnO , 5.85; CaO , 37.89; MgO , 9.0. G. A. Rankin and F. E. Wright noted the similarity between some of the properties ascribed to akermanite, and those of the rhombic calcium orthodisilicate, $3\text{CaO} \cdot 2\text{SiO}_2$, which they prepared. W. T. Schaller emphasized the ternary nature of the minerals of the melilite group, and he interpreted two analyses by F. Zambonini of a tetragonal Vesuvian mineral to mean that the formula of akermanite is $8\text{CaO} \cdot 4\text{MgO} \cdot 9\text{SiO}_2$. The graphic formula can be written:

J. B. Ferguson and H. E. Merwin did not succeed in preparing a compound of this composition, but they did obtain **magnesium dicalcium orthodisilicate**, $2\text{CaO} \cdot \text{MgO} \cdot 2\text{SiO}_2$, or $\text{Ca}_2\text{MgSi}_2\text{O}_7$, and they suggest that this is the true formula of akermanite. The interpretation of F. Zambonini's analyses require very little modification to fit them to this compound. The range of stability of this compound is indicated in Fig. 95, of the ternary system, $\text{MgO}-\text{CaO}-\text{SiO}_2$. The compound $2\text{CaO} \cdot \text{MgO} \cdot 2\text{SiO}_2$ forms no appreciable solid soln. The binary system $\text{CaO} \cdot \text{MgO} \cdot 2\text{SiO}_2$ and $2\text{CaO} \cdot \text{MgO} \cdot 2\text{SiO}_2$ has a eutectic at about 1360° , and 42 per cent. of the latter component; the binary system $2\text{CaO} \cdot \text{SiO}_2$ and $2\text{CaO} \cdot \text{MgO} \cdot 2\text{SiO}_2$ has a eutectic at about 1470° , and 91 per cent. of the latter component; while the system $\text{CaO} \cdot \text{SiO}_2$ and $2\text{CaO} \cdot \text{MgO} \cdot 2\text{SiO}_2$ has a eutectic and a broken liquidus curve as illustrated in Fig. 91. V. Schumoff-Deleano and E. Dittler measured the speed of crystallization of fused melilite.

The thin tabular crystals were found by J. H. L. Vogt to belong to the tetragonal system; and to be isomorphous with melilite and gehlenite. W. T. Schaller gave 3.12 for the sp. gr. of the mineral; and J. B. Ferguson and A. F. Buddington

found for the artificial crystals, 2.944 at 25°, and 2.955 for the glass. It is unusual for a glass to have a greater sp. gr. than the corresponding crystals. They are

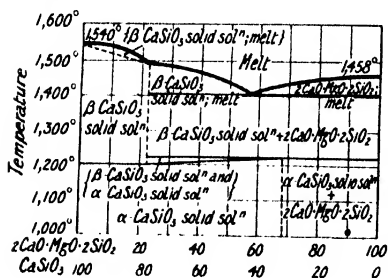

FIG. 91.—Equilibrium in the Binary System :
 $\text{CaSiO}_3\text{--}2\text{CaO.MgO.}2\text{SiO}_2$.

refractive index of the glass is 1.641 ± 0.002 . J. H. L. Vogt gave 0.187 for the sp. ht. between 0° and 100° , and 1200° for the m.p.; R. Akerman gave 1310° ; J. H. L. Vogt, 1175° ; and J. B. Ferguson and H. E. Merwin gave $1458^\circ \pm 5^\circ$ —vide Fig. 90. R. Akermann gave 404 cal. per gram for the total heat of fusion; and C. Doelter, and J. H. L. Vogt gave 90 cal. for the latent heat of fusion. J. B. Ferguson and A. F. Buddington studied the binary system $\text{Ca}_2\text{MgSi}_2\text{O}_7$ and gehlenite, $\text{Ca}_2\text{Al}_2\text{Si}_2\text{O}_7$ —vide velardinite.

J. B. Ferguson and H. E. Merwin² obtained evidence of the formation of **dimagnesium pentacalcium hexasilicate**, $5\text{CaO.}2\text{MgO.}6\text{SiO}_2$, in their study of the ternary system, CaO--MgO--SiO_2 . The field in the diagram belongs to a series of solid soln. which are not stable at their m.p., and which lie on or near the composition $5\text{CaO.}2\text{MgO.}6\text{SiO}_2$. The decomposition temp. of these solid soln. rise sharply as this composition is attained. The decomposition temp. is $1365^\circ \pm 5^\circ$. The compound appears in irregular elongated grains with the optic axial angle, $2Y$, about 80° ; and the indices of refraction, $\alpha=1.621$, $\beta=1.627$, $\gamma=1.635$.

The mineral *tremolite* was mentioned by H. B. de Saussure,³ in 1796, as being obtained from Val Tremola, south of St. Gotthard. It is an amphibole. R. J. Haüy called the mineral *grammatite*, *c'est-à-dire, marquée d'une ligne*—from $\gamma\rho\alpha\mu\mu\eta$, a line—in reference to a line in the direction of the longer diagonal which can be seen on transverse sections of some crystals. R. H. Haüy's term is rarely used.

A. G. Werner called a green mineral from Nordmarken, Sweden, *calamite*—from $\kappa\alpha\lambda\alpha\mu\iota\tau\epsilon$, a reed—was shown by E. F. Glocker, and A. Breithaupt to be tremolite. T. Thomson's *raphilite* from Lanark, Canada; E. Goldsmith's *hexagonite* from Edwards, St. Lawrence; and G. A. Kenngott's *nordensköldite* from Ruscola, Lake Onega, are all considered to be varieties of tremolite. G. A. König discussed the relation of hexagonite to tremolite.

Many analyses have been reported.⁴ These agree with the assumption that the idealized mineral is a **calcium trimagnesium tetrametasilicate**, $\text{CaMg}_3(\text{SiO}_3)_4$. Tremolite does not appear among the phases formed in the ternary system, MgO--CaO--SiO_2 , Fig. 94, under the conditions studied by J. B. Ferguson and H. E. Merwin. This, of course, does not mean that tremolite is not a chemical individual, for it may be a stable compound under another set of conditions. Ferrous oxide replaces up to about 3 per cent. of the magnesia. E. T. Allen, and J. K. Clement showed that up to about 2.5 per cent. of water may be present. This water is gradually lost on a rising temp. without any loss of homogeneity and with but a slight change in the optical properties. The dehydration is not complete until the powdered mineral has been heated to 900° . The water is not chemically combined, and is assumed to be adsorbed in solid soln. Tremolite varies in colour from white to dark grey, and is sometimes water-clear and colourless.

It may occur in compact granular masses, in fibrous aggregates; in long-bladed, short and stout, or thin-bladed crystals. L. H. Adams and E. D. Williamson found the compressibility, β , of actinolite to be $\beta=1.32 \times 10^{-6}$ between 0 and 10,000 megabars press. A. des Cloizeaux, G. Flink, K. Zimanyi, A. Michel-Lévy and A. Lacroix, and H. Rosenbusch have measured the optical properties of the crystals. The sp. gr. is 2.9–3.1. A. L. Fletcher gave 1269° – 1273° for the m.p. R. Cusack obtained a lower value. The optic axial angle, $2V$, is 87° – 88° ; and $2H=99^{\circ}$ – 101° . The extinction angle is 16° ; and the indices of refraction $\alpha=1.6065$, $\beta=1.6233$, and $\gamma=1.6340$. The optical character is negative. W. W. Coblenz found the ultra-red transmission spectrum has bands at 2.8, 4.8, 6, 7.4, and 8.2μ ; and the reflection spectrum has maxima at 8.7, 9.45, 10.03, and 11μ . G. A. Kenngott found that in contact with water the calcined or uncalcined mineral has an alkaline reaction.

When the ferrous oxide in tremolite approaches 3 per cent., it passes into the mineral *actinolite*, but there is no sharp line of demarcation. The ferrous oxide is supposed to be present as ferrous tricalcium tetrametasilicate, $\text{Ca}_3\text{Fe}(\text{SiO}_3)_4$, and to form a series of solid soln. with tremolite proper. A. Cronstedt⁵ called the mineral *Strålskörl*; and A. G. Werner, *Strahlstein*, which R. Kirwan translated to *actinolite*, from *deriv*, a ray; and *lithos*, stone. R. J. Haüy used the term *actinolite*; and J. C. Delaméthière, *schort verte du Zillerthal*, or *zillerthite*. Many analyses have been reported.⁶ E. T. Allen and J. K. Clement found that actinolite contains up to about 3 per cent. of water, which is retained over 100° . The mineral is green, and it occurs in crystals as in tremolite, or fibrous, columnar, or massive. The sp. gr. is 3.0–3.2. The optical constants were investigated by A. des Cloizeaux, A. Michel-Lévy and A. Lacroix, and K. Zimanyi; and the pleochroism, by A. Michel-Lévy and A. Lacroix, and G. Tschermak. R. Cusack gave 1272° – 1288° for the m.p. of green actinolite; and A. L. Fletcher, 1322° – 1338° . E. Reymond studied the action of chlorine and of hydrogen chloride on actinolite; and V. Iskyul, the action of hydrochloric acid, and the solubility of the silica in actinolite.

A tough, compact, fine-grained tremolite or actinolite, varying in colour from a cream to a dark green, is called *nephrite*—from *νεφρός*, a kidney—because it was formerly supposed to have a medicinal value in diseases of the kidney. The term *jade* is applied generally to various mineral substances which have the appearance of nephrite, and *jadeite*. The latter is a kind of soda-spodumene (*q.v.*). Jade was used by early man for utensils and ornaments of great beauty and variety. Jade has been found among the relics of early man—e.g. in the remains of the lake-dwellers of Switzerland, at various places in France, in Mexico, Greece, Egypt, Asia Minor, etc. The quarries in Central Asia in the Kuen Lun Mts. have been worked by the Chinese for 2000 years. The greenstone ornaments of the Maoris of New Zealand are made from nephrite. The subject has been much discussed.⁷ Numerous analyses have been reported.⁸ The analyses have been discussed by S. L. Penfield, A. Damour, and L. Colomba. The crystals have been investigated by G. vom Rath, J. D. Dana, W. C. Brögger, A. W. G. Bleock, M. Bauer, A. des Cloizeaux, F. Borworth, etc. S. L. Penfield gave for the axial ratios of the monoclinic crystals $a:b:c=1.103:1:0.613$, and $\beta=72^{\circ}44'$. The microstructure has been studied by F. W. Clarke and G. P. Merrill, A. Arzruni, A. des Cloizeaux, E. Cohen, J. A. Krenner, etc. H. R. Bishop gave a collection of about 500 samples of nephrite, and 100 of jadeite. The average for nephrite is 2.9565, and for jadeite, 3.3202. The hardness of nephrite is nearly 6, and of jadeite, nearly 6.5. The results of the impact test have been reported by H. R. Bishop, H. von Schlagintweit, and A. Rosival; the crushing strength, by H. R. Bishop, and L. Jaczewsky; the elastic constants, by H. R. Bishop, and W. Voigt; the acoustic qualities, by H. R. Bishop. The optical properties have been investigated by A. des Cloizeaux, J. A. Krenner, E. Cohen, M. Bauer, A. Arzruni, A. Michel-Lévy and A. Lacroix, H. R. Bishop, L. Mrázec, S. Franchi and L. Colomba, etc. The fusibility has been studied by C. Doelter, V. S. Deleano, etc., and the actions of acids and salt soln., by J. Lemberg. C. Doelter has compiled data pertaining to nephrite and jadeite.

§ 30. The Complex Silicates of Magnesium

R. C. Wallace¹ found that in the binary system, $\text{MgSiO}_3\text{--Li}_2\text{SiO}_3$, two series of mixed crystals were formed, with a break from 50 to about 75 per cent. of magnesium metasilicate, Fig. 92. The eutectic temp. was 876° . No lithium magnesium metasilicate appeared. In the system $\text{MgSiO}_3\text{--Na}_2\text{SiO}_3$, all the mixtures between 20 and 80 per cent. magnesium metasilicate solidified to a glass, Fig. 93. No sodium magnesium metasilicate was produced. F. Focke obtained a

FIGS. 92 and 93.—Freezing Curves of Binary Mixtures of Magnesium Metasilicate with Lithium and Sodium Metasilicates.

green mineral resembling serpentine from Wildkreuzjoch, Tyrol, and he called it *nemaphyllite*. It contained 42.49 per cent. SiO_2 ; 0.40, Al_2O_3 ; 4.63, Fe_2O_3 ; 37.60, MgO ; 0.72, CaO ; 2.11, Na_2O ; and 13.11, H_2O . The sp. gr. was 2.6; hardness, 3; cleavage, perfect; and the birefringence, negative and weak.

The colourless, transparent mineral *tainiolite*, obtained by G. Flink from Narsarsuk, Greenland, has a composition corresponding with $\text{H}_2(\text{Li}, \text{Na}, \text{K})_2(\text{Mg}, \text{Fe})_2(\text{SiO}_3)_3$, and in the ideal case is a *potassium magnesium metasilicate*. The

name is derived from *ραβία*, a band or strip; *λίθος*, a stone—in allusion to the form of the crystals. The monoclinic crystals resemble mica; the axial ratios are $a : b : c = 0.5773 : 1 : 3.2743$. The birefringe is negative and weak; the optic axial angle $2E = 50^\circ$; the sp. gr. 2.86; and the hardness 2.5–3.0. The mineral is slowly but completely decomposed by hydrochloric acid. According to A. Duboin, no silicate is obtained when silica is added to a fused mixture of magnesia and potassium fluoride, but if one part of magnesia and 4 parts of silica are dissolved in fused potassium fluoride and the product is afterwards fused with potassium chloride and kept at a red heat for about three days, **potassium magnesium trisilicate**, $MgO.K_2O.3SiO_2$, is obtained in hexagonal crystals, with a negative axis, and flattened parallel with the base. Its sp. gr. at 0° is 2.55, and it is readily attacked by acids.

P. Berthier,² F. C. Achard, W. A. Lañpadius, and N. G. Sefström made a number of glasses by heating various mixtures of lime, magnesia, and silica. Thus, $CaO : MgO : SiO_2 = 1 : 1 : 2$; $1 : 2 : 3$; $2 : 1 : 3$; $1 : 1 : 3$ were formed. Some of these crystallized. There is, however, nothing to show what chemical individuals were formed. C. Mutschler and E. C. F. von Gorup-Besanez obtained from the ash of the *calamus rotang* what they regarded as a compound $CaO.MgO.4SiO_2$. Here again the individuality of the product was not established.

The very rare mineral **monticellite** was named after T. Monticelli: it was found in yellowish crystals at Mount Vesuvius. The mineral belongs to the olivine family which includes forsterite, fayalite, and tephroite. The crystals were first described by H. J. Brooke³ in 1831. N. Nordenskjöld called it *scacchite* (misprinted *sacchite*), after A. Scacchi. A. Breithaupt, and L. Liebener and J. Vorhauer called a greenish-grey product *batrachite*—from *βάτραχος*, a frog—in reference to the colour. The analyses by C. F. Rammelsberg, G. vom Rath, F. A. Genth, G. Tschermak, S. L. Penfield and E. H. Forbes, P. von Jeremejeff, J. Lemberg, etc., correspond with **magnesium calcium orthosilicate**, $CaMgSiO_4$. N. G. Sefström obtained a glass of this composition by fusing the constituents together. V. Pöschl, and V. S. Deleano studied the fusion curves of mixtures of magnesium and calcium orthosilicates. The latter found that a eutectic is produced at 1400° with about 80 per cent. of magnesium orthosilicate. No monticellite was formed, and it was assumed that the occurrence of this mineral in volcanic products shows that an *agent mineralisateur* was present. Mixtures rich in calcium orthosilicate disintegrate on cooling. Enstatite is formed, and the disintegration of calcium orthosilicate occurs in the presence of up to 50 per cent. of enstatite. A. F. Hallimond obtained crystals of monticellite from a steel-works mixer slag, and of the composition $Ca(Mg, Fe, Mn)SiO_4$. J. B. Ferguson and H. S. Merwin have shown the field of stability of monticellite in the ternary system, $MgO-CaO-SiO_2$, Fig. 95. P. Hermann showed that solid soln. are formed between forsterite and monticellite; and J. B. Ferguson and H. E. Merwin place the limit at about 10 per cent. of forsterite. J. H. L. Vogt found crystals of monticellite in slags; and H. le Chatelier, in portland cements. V. Pöschl, and J. Morozewicz prepared products containing monticellite by fusing the component silicates, and the former gave for mixtures of forsterite and lime-olivine, i.e. of magnesium and calcium orthosilicate:

Mg_2SiO_4	100	90	80	70	50	30	20	0
Sp. gr.	3.11	3.04	3.01	2.96	2.90	2.88	3.04	3.1
M.p. (mean)	1600°	1340°	1327°	1315°	1310°	1302°	1335°	1600°

V. Pöschl also studied the ternary system, $Mg_2SiO_4-Ca_2SiO_4-Fe_2SiO_4$. J. B. Ferguson and H. E. Merwin's attempts to isolate monticellite were not successful; a mixture of crystals of calcium orthosilicate and the forsterite-monticellite solid soln. was always obtained.

The crystals of monticellite, according to G. vom Rath, belong to the rhombic system, and they have the axial ratios $a : b : c = 0.43369 : 1 : 0.57569$. H. J. Brooke,

and A. Scacchi made some observations on this subject. J. B. Ferguson and H. E. Merwin's products contained crystals of monticellite in equant grains, without facets. As emphasized by N. L. Bowen, the optic axial angle is large, $2V=85^{\circ}-90^{\circ}$. F. A. Genth gave for the sp. gr., 3.108; S. L. Penfield and E. H. Forbes, 3.022-3.047; G. Tschermak, 3.098; and G. vom Rath, 3.054 (batrachite). The hardness is 5-6. C. Doelter gave $1180^{\circ}-1200^{\circ}$ for the m.p. J. Joly gave $0.1963-0.2113$ for the sp. ht. S. L. Penfield and E. H. Forbes gave for the indices of refraction $\beta=1.6584$ for Li-light, or for Na-light, $\alpha=1.6506$, $\beta=1.6616$, and $\gamma=1.6679$; and for the birefringence, $\gamma-\alpha=0.0174$. J. B. Ferguson and H. E. Merwin found for artificial crystals $\alpha=1.638-1.640$; $\beta=1.646$; and $\gamma=1.651-1.655$. A. des Cloizeaux investigated the optical properties of monticellite. V. Pöschl obtained 1460° , and J. B. Ferguson and H. E. Merwin, 1502° for the m.p. E. Kittl found that in the crystallization of the glass, 1600 nuclei are present per sq. cm. According to G. Tschermak, when monticellite is treated with acids, orthosilicic acid separates out. F. Cornu found the moistened powder reacts alkaline towards litmus. F. Sestini, and J. Lemberg examined the effect of water on the mineral; C. Doelter, the effect of dry hydrogen chloride on the heated mineral; and also the effect of a soln. of sodium carbonate. W. Suida found that the mineral is feebly stained by basic aniline dyes. The monticellite changes on weathering into serpentine, fassaite, etc. The metamorphoses have been investigated by P. von Sustrinsky, G. vom Rath, J. Lemberg, K. Oebbeke, R. Brauns, etc. E. S. Larsen and W. F. Foshag⁴ obtained a colourless or pale green mineral resembling monticellite from the limestone of Crestmore, California. The composition corresponded with $\text{Ca}_3\text{Mg}(\text{SiO}_4)_2$, **magnesium tricalcium diorthosilicate**, and they called the mineral *merwinite*—after H. E. Merwin. The mineral is monoclinic; the cleavage (010) is perfect; lamellar twinning occurs on the prism faces, forming an angle of 42.5° ; the optical axial angles, $2V=66.5^{\circ}$; the axial angle $a:c=36^{\circ}$; the sp. gr. is 3.150; the hardness, 6; and the indices of refraction are $\alpha=1.708$, $\beta=1.711$, and $\gamma=1.718$. It readily dissolves in hydrochloric acid.

P. C. Abilgaard,⁵ and J. C. Delam  therie applied the term *malaconite* to a bluish-grey, or greyish-green mineral from Sala, Sweden, which was softer than the associated felspar, hence the name was adapted from *μαλακός*, soft. It is related with the mineral *salite* or *sahlite* which has a similar colour. Salite was found in Sala, Sweden, by M. F. R. d'Andrada, and it was analyzed by L. N. Vauquelin. The granular variety, with more or less indistinct crystals, from Arendal was described by P. C. Abilgaard, and M. F. R. d'Andrada, and called *coccolite*, from *κόκκος*, a grain. It, too, was analyzed by L. N. Vauquelin. B. Bonvoisin described greenish prismatic crystals of a mineral from the Mussa Alp, Ala Valley, Piedmont; and a white, greyish-white, or apple-green, crystalline aggregate from the same locality. The former was called *alakite*, after the Ala Valley, and the latter *mussite*, from the Mussa Alp. R. J. Ha  y showed that both these minerals belong to one mineral species, which he designated **diopside**, from *δύς*, double; and *ὄψις*, appearance. He also showed that salite, coccolite, and malaconite are varieties of diopside.

T. Scheerer's *traversellite*, from Traversella, Piedmont, is a fibrous aggregate of the same mineral. The mineral named *baikalite* by H. M. Renovanz⁷ is from the Lake Baikal district, Siberia. It was also described by R. J. Ha  y, and D. L. G. Karsten. The bluish-white mineral *canaanite* of F. Alger from Canaan, Connecticut, was described by C. H. Hitchcock, and J. D. Dana. The *funkite* of A. P. Duf  r  y is a dark olive-green coccolite from Boks  ter, G  thland. N. von Kokscharoff's *lawroffite*, *lawrovite*, or *lawrovite* is a diopside coloured green by vanadium, and came from Lake Baikal, Siberia. The *proteite* of E. F. Glocker, and A. Breithaupt from Zillerthal, Tyrol, is a form of *alakite* and *mussite*. H. von Eckermann called a fluoriferous diopside, $\text{Ca}(\text{Mg}, \text{Fe})(\text{SiO}_3)_{1.5}\text{Mg}(\text{OH}, \text{F})_2$, from Mansj   Mountains, *mansejoite*.

The reported occurrences of diopside as a rock-forming mineral are very

numerous; and hundreds of analyses have been made. The composition of colourless or white diopside approximates very closely to that required for **magnesium calcium dimetasilicate**, $\text{CaMg}(\text{SiO}_3)_2$. E. T. Allen and J. K. Clement found that diopsides may have up to about one per cent. of water which is only lost completely and continuously by heating the mineral up to 900° . The water is adsorbed or in solid soln. E. A. Wülfing regarded the ferruginous diopsides as being members of a series of isomorphous mixtures with varying proportions of the metasilicates: diopside proper, $\text{CaMg}(\text{SiO}_3)_2$; hedenbergite, $\text{CaFe}(\text{SiO}_3)_2$; and $\text{MgFe}(\text{SiO}_3)_2$. The structure has been discussed by P. Groth, L. Duparc and T. Hornung, G. Becker, J. H. L. Vogt, R. Scharizer, and W. Vernadsky. J. Jakob applied the co-ordination theory and represented diopside:

Assuming that the ferrous oxide is present as $\text{CaFe}(\text{SiO}_3)_2$, the ratio of $\text{CaMg}(\text{SiO}_3)_2$ to $\text{CaFe}(\text{SiO}_3)_2$, ranges upwards, passing through 8:1, 7:1, 4:1, 3:1, 2:1, to nearly 1:1; then appear the varieties of hedenbergite and schefferite in which the ratio passes through 2:3, 1:2, and 1:9. In 1858, C. F. Rammelsberg emphasized the importance of distinguishing between ferrous and ferric oxides in the analyses of these minerals. The proportions of alumina and ferric oxide rise from zero until the diopside pyroxenes pass into augites. These monoclinic pyroxenes can then be approximately arranged in two classes according as the sesquioxides are or are not present as essential constituents:

Monoclinic pyroxenes	{ without sesquioxides	DIOPSIDES
	{ with sesquioxides	AUGITES

A greenish variety, coloured with chromic oxide, is called *chrome-diopside*, and it was described by A. Knop, E. Jannetaz, R. Scharizer, etc. The occurrence of diopside in meteorites was discussed by N. S. Maskelyne, and S. Meunier; and in

slags by F. von Kobell, G. vom Rath, L. Gruner, P. S. Gilchrist, T. Scheerer, C. F. Rammelsberg, J. E. L. Hausmann, C. C. von Leonhard, J. Nöggerath, F. Sandberger, G. J. Brush, N. S. Maskelyne, C. Vélain, E. Mallard, P. W. von Jeremejeff, A. Knop, J. H. L. Vogt, etc.

P. Berthier⁸ made diopside by fusing a mixture of the constituents. G. Lechartier used calcium chloride as a flux; J. J. Ebelmen, boric oxide; C. J. St. C. Deville, F. Fouqué and A. Michel-Lévy, A. Lacroix, E. Hussak, A. Becker, P. Hautefeuille, A. Gorgeu, and C. Doelter made observations with respect to diopside analogous to those indicated in connection with the other magnesium silicates. L. Bourgeois made diopside by suspending a block of marble in fused basalt. G. Rose observed crystals of

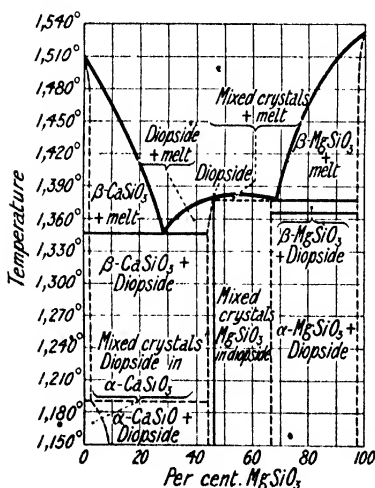

FIG. 94.—The Equilibrium Conditions in the Binary System: CaSiO_3 - MgSiO_3 .

diopside in some augite which had been fused and cooled. The formation of diopside and augite in the crystallization of fused silicates has been observed

by J. Morozewicz, G. Medanich, K. Petrasch, H. H. Reiter, C. Doelter, etc. H. J. Johnston-Lavis observed crystals of pyroxene on fossil bones in the volcanic tufa of Faiano, Nocera, and assumed that the mineral was formed under little press., and at a temp. insufficient to carbonize or even discolour the organic matter of the bones. L. Appert and J. Henrivaux found crystals of diopside were formed when ordinary window-glass was kept for some time just below the softening temp. A. Daubrée made diopside by the action of the water of Plombières on a hot glass tube. V. Pöschl prepared diopside by the union of magnesium and calcium metasilicates. V. S. Deleano found that the binary system, $\text{Mg}_2\text{SiO}_4\text{-CaSiO}_3$, has a eutectic at about 1300° with 90 molar per cent. of calcium metasilicate. The system is really a quaternary one because periclase and enstatite are formed.

In the system of $\text{Ca}_2\text{SiO}_4\text{-MgSiO}_3$ there is a eutectic with about 80 molar per cent. of magnesium metasilicate at about 1300° . E. T. Allen and W. P. White studied the conditions of formation of diopside in the binary system, $\text{CaSiO}_3\text{-MgSiO}_3$. The range of stability of diopside is indicated in Fig. 94. The best crystals were obtained by heating a glass of the composition $\text{MgCa}(\text{SiO}_3)_2$ in a flux of calcium chloride, in an atm. of dry hydrogen chloride at 1000° for a week. J. B. Ferguson and H. E. Merwin found the limits of stability of diopside in the ternary system, CaO-MgO-SiO_2 , Fig. 95; P. Niggli described this system; and N. L. Bowen, the relations in the ternary system, diopside-forsterite-silica.

J. B. Ferguson and H. E. Merwin's conc. diagram, showing the limits of the fields of stability of the various phases in wt. per cent., is shown in Fig. 95. The range for

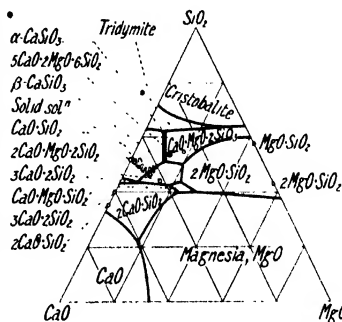

FIG. 95.—The Limits of the Different Phases on the Concentration Diagram of the Ternary System: CaO-MgO-SiO_2 (wt. per cent.).

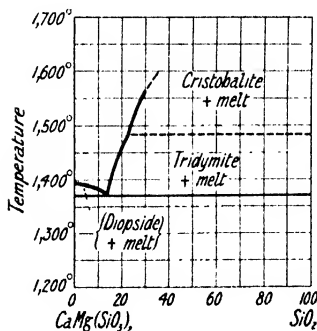

FIG. 96.—Freezing-point Curves of the Binary System: Diopside-Silica.

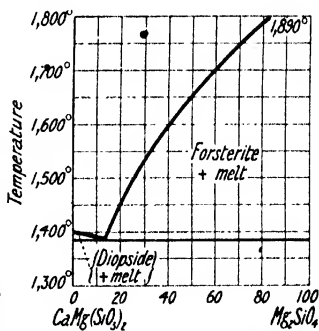

FIG. 97.—Freezing-point Curves of the Binary System: Diopside-Forsterite.

β -wollastonite is too small to appear in the diagram. There are four complex calcium magnesium silicates, namely: (i) $5\text{CaO} \cdot 2\text{MgO} \cdot 6\text{SiO}_2$; (ii) akermanite, $2\text{CaO} \cdot \text{MgO} \cdot 2\text{SiO}_2$; (iii) monticellite, $\text{MgO} \cdot \text{CaO} \cdot \text{SiO}_2$, or MgCaSiO_4 ; and (iv) diopside, $\text{MgO} \cdot \text{CaO} \cdot 2\text{SiO}_2$ or $\text{MgCa}(\text{SiO}_3)_2$. Diopside does not form a solid soln. with

silica, forsterite, or pseudowollastonite; nor does it form a solid soln. to any marked degree with $2\text{CaO} \cdot \text{MgO} \cdot 2\text{SiO}_2$; but it does form a continuous series of solid soln. with clino-enstatite, which crystallizes in forms corresponding with the monoclinic pyroxenes. N. L. Bowen has made a special study of the binary and ternary systems with diopside, forsterite, and silica as components. Fig. 97 shows that no higher silicate is formed with diopside. The topography of the ternary system is shown in Fig. 98, and the isothermal f.p. curves in Fig. 99. N. L. Bowen found that

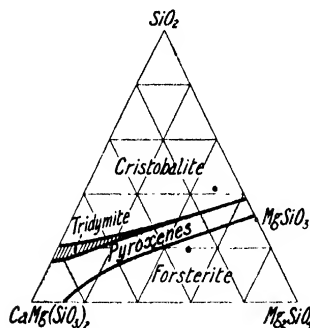

FIG. 98.—Ternary System: Diopside-Forsterite-Silica.

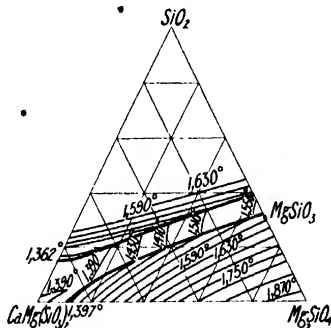

FIG. 99.—Isothermal Freezing Curves in the Ternary System: Diopside-Forsterite-Silica.

there is a eutectic with 88 per cent. of diopside and 12 per cent. of forsterite at a temp. about 4° – 5° lower than the m.p. of diopside, Fig. 99. The compositions of the phases worked out by J. B. Ferguson and H. E. Merwin are illustrated by the triangular diagram, Fig. 98. V. Pöschl measured the sp. gr., m.p., and angle of extinction of mixtures of enstatite and diopside, and found:

Diopside	0	25	40	50	60	75	100 per cent.
Sp. gr.	3.2	3.12	3.05	2.98	3.25	3.04	3.08
M.p.	1375°	1320°	1300°	1300°	1295°	1300°	1300°
	1400°	1350°	1325°	1320°	1315°	1320°	1325°
Extinction	—	—	—	—	30°	37°	32°

G. Zinke examined the products obtained by cooling molten mixtures of the two compounds, and he likewise obtained a series of pyroxenes of varying composition. The nature, but not the composition, of the phases at any temp. during the cooling

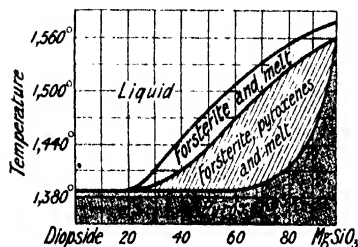

FIG. 100.—Nature of the Solid Phases in Cooling Molten Mixtures of Diopside and Magnesium Metasilicate.

is illustrated by N. L. Bowen's diagram, Fig. 100. With a molten mixture containing, say, $19\text{MgCa}(\text{SiO}_3)_2 + 81\text{MgSiO}_3$, forsterite begins to crystallize out at 1552° , and continues crystallizing down to 1523° , when pyroxene also appears. The three phases coexist down to 1420° , when both forsterite and liquid disappear, and all consists of pyroxene. N. L. Bowen discussed the effect of the sp. gr. and viscosity of the molten magma on the crystallization.

P. Eskola said that his attempts to make *strontia-diopside* and *baryta-diopside* were not successful. There is no evidence that the metasilicates of barium or strontium and magnesium form a double compound. This is remarkable, especially in the case of strontium, which in other ways showed such a close similarity with

calcium. P. Eskola pointed out that in compounds in which the lime may possibly be replaced by magnesia and ferrous iron, it cannot be replaced by strontia or baryta. Accordingly, barium and strontium compounds form mixed crystals with lime and alkali minerals, but not with ferromagnesian minerals.

The **colour** of diopside, or calcium magnesium dimetasilicate in the limiting case, is water-clear, or white; the mineral is variously tinted green, and various shades of yellow, red, and brown, according to the proportion of ferrous oxide and other impurities which may be present. The compound was found by E. T. Allen and W. P. White to crystallize readily, usually in the form of radiating prismatic individuals intricately intergrown and overlapping. There are often fine bubble-like inclusions or cavities in the crystalline mass; these are either tabular in shape and parallel with the prismatic elongations of the crystallites, or else they are irregular. The cavities are probably due to the shrinkage accompanying the crystallization of the glass; they are rarely observed in the crystals from the molten calcium chloride flux. Both the natural and artificial crystals belong to the monoclinic system, and the artificial crystals have the axial ratios $a : b : c = 1.096 : 1 : 0.591$, and the natural crystals $a : b : c = 1.0934 : 1 : 0.5894$. The differences are within the limits of experimental error. F. Zambonini gave $a : b : c = 1.0503 : 1 : 0.5894$, and $\beta = 90^\circ 9'$ for the natural crystals. Observations on the native diopside crystals have been made by E. Artini, R. B. Hare, A. Schmidt, H. Baumhauer, J. Götz, K. Busz, G. vom Rath, G. Flink, J. Lehmann, A. Streng, F. Hessenberg, N. von Kokscharoff, A. des Cloiseaux, G. la Valle, A. Michel-Lévy, G. Norden-skjöld, G. Rose, J. D. Dana, etc. F. Rinne, and R. Grossmann measured the change in the angles on heating the crystals. F. Rinne obtained **X-radiograms** of the mineral; and the shape and size of the unit cells of diopside, and diopside-like pyroxenes have been studied by R. W. C. Wyckoff and co-workers. The **twinning** of the artificial crystals after (100) was found by E. T. Allen and W. P. White to be common, while polysynthetic twinning after (100) was rare. The twinning has been studied by F. Becke. In the natural crystals twinning by the (100)-face is common; the crystal may be traversed by twin lamellae parallel to that face, and sometimes also parallel to the (001)-face. The crystals of the mineral generally appear to be holosymmetric; but the two ends of the prism are sometimes different, indicating that the mineral probably possesses only a plane of symmetry, and not a digonal axis perpendicular to it. This is confirmed by the observations of E. A. Wülfing, H. Baumhauer, and G. Greim on the **corrosion figures** produced on the prism faces by hydrofluoric acid. F. Mohs showed that the diopsides from Sala and the Ala Valley possess a kind of **cleavage** parallel to the (100)- and the (001)-faces. These are not true cleavages, but rather partings due to these faces being glide-planes and planes of secondary twinning. The partings occur only at intervals, and are not uniformly distributed through the crystals as would be the case with true cleavages. The partings are supposed to be produced by press. They have been studied by A. H. Phillips, J. H. Teall, G. W. Hawes, G. vom Rath, L. van Werveke, A. Osann, O. Mügge, J. W. Judd, T. Scheerer, G. Rose, F. Zirkel, F. Becke, etc. E. Kittl's measurement of the **speeds of crystallization** of three samples of diopside at different temp. are shown in Fig. 101. There is a well-defined maximum about 1270° ; and he found that in the crystallization of the glass, 1.3-9.3 nuclei are present per sq. cm. Measurements were also made by V. Schumoff-Deleano and E. Dittler. The plane of the optic axes is the plane of symmetry (010). The **optic axial angles** $2V = 59^\circ 3' \pm 1.0^\circ$, and $2E = 114^\circ$. E. A. Wülfing found $2V = 58^\circ 40'$ for the natural crystals; and with Li-light, $59^\circ 28'$; with Na-light, $59^\circ 15'$; and with

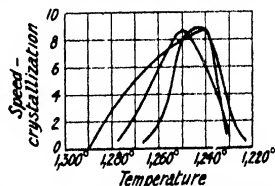

FIG. 101.—Effect of Temperature on the Speed of Crystallization of Diopside.

Tl-light, $58^{\circ} 58'$; the numbers for a ferruginous diopside are respectively $59^{\circ} 48'$, $59^{\circ} 52'$, and $59^{\circ} 38'$. E. T. Allen and W. P. White measured the optical axial angles of solid soln. with mixtures containing 28–95 per cent. of magnesium metasilicate. N. L. Bowen's values for the optical axial angles, $2V$, of solid soln. of diopside and clinoenstatite were :

Diopside	100	75	65	56	37	19	0 per cent.
$2V$	59°	56°	47°	40°	smell	20°	53°

G. Zinke made some measurements of this constant. *G. Tschermak, F. Herwig, C. Doelter, F. J. Wiik, G. Flink, and A. Schmidt have made observations on this subject, and in general, the angle increases as the proportion of iron is raised. A. des Cloizeaux measured the effect of temp. on the optic axis.

E. T. Allen and W. P. White measured the **specific gravity** of various combinations of calcium and magnesium metasilicates, and found

MgSiO ₃	0	20	46.3	50	60	70	72	72	100 per cent.
Sp. gr.	2.912	3.046	3.236	3.245	3.229	3.205	3.196	3.194	3.193
Sp. vol.	0.3434	0.3283	0.3090	0.3082	0.3096	0.3120	0.3129	0.3130	0.3132

The **specific volume** curve is shown in Fig. 102. There are three distinct curves : *AB* represents mechanical mixtures of pseudowollastonite and diopside ; *BC*, solid soln. of diopside with magnesium silicate ; and *CD*, solid soln. of magnesium silicate with diopside. The sp. gr. of artificial diopside is 3.245. J. W. Retgers inferred that diopside is a chemical compound because its sp. vol. cannot be calculated additively from the sp. vol. of its constituents. E. T. Allen and W. P. White gave 3.270–3.275 for the crystals at $25^{\circ}/25^{\circ}$, and 2.830 for the glass at $30^{\circ}/25^{\circ}$. This gives an idea of the expansion which occurs in the process of melting. The sp. gr. of crystals from Alaska was 3.268 at $25^{\circ}/25^{\circ}$. The sp. gr. of many of the specimens which have been analyzed have been determined—*vide supra*—and the results show that the sp. gr. increases with the proportion of ferrous oxide up to about 3.53. V. Pöschl found the sp. gr. of the artificial mixtures or solid soln. is almost always smaller than with the natural crystals, presumably because the former have more pores and cavities. He found the physical characters of solid soln. of diopside and hedenbergite varied continuously, but not linearly, with the composition. Thus :

FIG. 102.—Specific Volume Curves in the Binary System: MgSiO₃—CaSiO₃.

tion of ferrous oxide up to about 3.53. V. Pöschl found the sp. gr. of the artificial mixtures or solid soln. is almost always smaller than with the natural crystals, presumably because the former have more pores and cavities. He found the physical characters of solid soln. of diopside and hedenbergite varied continuously, but not linearly, with the composition. Thus :

Diopside	100	90	80	70	60	50	40	30	0
Hedenbergite	0	10	20	30	40	50	60	70	100
Per cent. FeO	0	2.40	5.00	7.03	9.98	12.57	14.87	17.07	25.00
Sp. gr.	3.08	2.87	2.90	2.96	2.98	3.01	3.16	3.26	3.53
M.p.	1325°	1265°	1250°	1240°	1230°	1225°	1210°	1200°	1140°
Axial angle	32°	36°	38°	$43^{\circ} 40'$	$45^{\circ} 50'$	47°	$49^{\circ} 20'$	50°	$50^{\circ} 30'$

The **hardness** of diopside is about 5. L. H. Adams and E. D. Williamson found the **compressibility** of diopside to be $\beta = 1.09 \times 10^{-6}$ between 0 and 10,000 megabars press.

F. Pfaff found the coeff. of **thermal expansion** between 0° and 100° in the *a*-direction to be 0.0008125; in the *b*-direction, 0.0016963; and in the *c*-direction, 0.001707; thus making the coeff. of cubical expansion 0.002330. P. E. W. Oeberg gave 0.1871, 0.192, and 0.2036 for the **specific heat** of diopside between 0° and 100° ; F. E. Neumann gave 0.1906; and H. Kopp, 0.184 between 19° and 50° . W. P. White gave for the mean sp. ht. of artificial diopside between ordinary temp. and

	100°	500°	700°	900°	1100°	1300°
Mean sp. ht.	0.1912	0.2309	0.241	0.2483	0.2563	0.2603
True sp. ht.	—	0.262	0.272	0.281	0.286	—

E. T. Allen and W. P. White gave 1381° for the **melting point** of artificial diopside; A. L. Day and R. B. Sosman, 1395°; E. Kittl, 1280°–1310°; J. H. L. Vogt, 1225°; V. Pöschl, 1325°; and A. L. Fletcher, 1237°–1245°—R. Cusack obtained a lower value. C. Doelter found diopside begins to melt at 1305°, and is quite fluid at 1345°. V. S. Deleano gave 1280°–1310°, and E. Dittler 1300°–1320° for the m.p., and H. Leitmeier, by very slowly raising the temp. during 24 hrs., obtained 1305°–1315°. C. Doelter found for diopside from Ala Valley 1250°–1270°; from Zermatt, 1270°–1300°; and from Zillertal, 1300°–1340°. The results with native diopside depend also on the nature of the impurities, and the m.p. is reduced when ferrous oxide is present; with mixtures of $\text{CaFe}(\text{SiO}_3)_2$ and $\text{CaMg}(\text{SiO}_3)_2$, V. Pöschl found the m.p. ranged from 1140°–1325° respectively, and he gave for mixtures of enstatite and diopside:

Diopside	100	75	60	50	40	25	0 per cent.
Sp. gr.	3.08	30.4	3.25	2.98	3.05	3.12	3.2
M.p. (mean)	1312°	1310°	1305°	1310°	1312°	1325°	1387°
Axial angle	32°	37°	39°	—	—	—	—

H. Leitmeier observed that the m.p. is reduced when the mineral is very finely powdered. R. Akermann gave 444 cal. per gram for the **total heat of fusion**; while C. Doelter, 94 cal., and J. H. L. Vogt, 100 cal., for the latent heat of fusion. G. Tammann gave for the **heat of solution** of diopside crystals in 100 grms. of 30 per cent. hydrofluoric acid mixed with 250 c.c. of 1*N*-hydrochloric acid 472 cal. per gram; and for diopside glass, 565 cal. Hence the **heat of crystallization** is 93 cal. per gram. O. Mulert obtained a similar result.

E. T. Allen and W. P. White gave for the **indices of refraction** of artificial diopside in Na-light, $\alpha=1.664$, $\beta=1.671$, and $\gamma=1.694$, each ± 0.002 . This gives for the **birefringence** $\gamma-\alpha=0.030$, $\gamma-\beta=0.023$, and $\beta-\alpha=0.007$. They also measured the indices of refraction, and extinction angles of solid soln. of combinations with 28–95 per cent. of magnesium metasilicate. Observations on the mineral were made by A. des Cloizeaux, E. Dufet, E. A. Wülfing, A. Schmidt, A. Michel-Lévy and A. Lacroix, G. Nordenskjöld, etc. G. Flink and E. A. Wülfing found:

Colour	α			β			γ		
	Li	Na	Tl	Li	Na	Tl	Li	Na	Tl
White	1.6675	1.6710	1.6749	1.6744	1.6780	1.6818	1.6962	1.7000	1.7045
Yellowish-green . .	1.6697	1.6734	1.6770	1.6767	1.6804	1.6838	1.6990	1.7029	1.7057
Grass green	—	—	—	1.6889	1.6959	1.7003*	—	—	—
Dark green	—	—	—	1.7005	1.7047	1.7106	—	—	—
Black	1.6956	1.6986	1.7030	1.7028	1.7057	1.7103	1.7244	1.7271	1.7326

N. L. Bowen's values for the maximum indices of refraction of the solid soln. of diopside and clinoenstatite were:

Diopside	100	92	84	75	65	56	37	19	0 per cent.
Max.	1.694	1.692	1.684	1.684	1.678	1.675	1.671	1.665	1.660
Min.	1.664	1.664	1.662	1.660	1.655	1.655	1.653	1.651	1.651

E. T. Allen and W. P. White found the **extinction angles** on the clinopinacoid or (010)-face to be $-38.5^\circ \pm 1^\circ$; and on the prism or (110)-face $-39.9^\circ \pm 10$. Measurements were made by G. Tschermak, F. J. Wiik, C. Doelter, F. Herwig, P. Mann, W. C. Brögger, H. Rosenbusch, G. Flink, etc. The effect of ferrous oxide on the extinction angle on the (010)-face is:

FeO per cent. . . .	2.91	3.09	3.49	4.50	17.34	28.29
Extinction	36° 5'	36° 50'	37° 10'	39° 10'	46° 45'	47° 50'

G. Flink found for a white diopside, the extinction angle $38^\circ 11\frac{1}{2}'$ with red light, $38^\circ 31\frac{1}{2}'$ with yellow light, and $37^\circ 54\frac{1}{2}'$ with green light. F. J. Wiik represented the relation between the extinction angle and the per cent. x of ferrous oxide by:

Extinction angle = $35.5 + 0.8719x - 0.0167x^2$; other formulæ have been given for other types of mineral. E. T. Allen and W. P. White, and A. Michel-Lévy and A. Lacroix measured the effect of the angle of the prism face with the orthopinacoid or (100)-face, on the extinction, and found a rapid rise for the first 40° ; and for faces near the clinopinacoid, the changes are slight. Diopside is optically positive. N. L. Bowen's values for extinction angles, ϕ , of solid soln. of diopside and clinostatite were:

Diopside	100	93	74.5	56	40.5	37	19	0 per cent.
ϕ	38.5°	37.5°	36°	34°	31.5°	30°	26°	22°

The interference figures have been studied by H. de Sénarmont, and A. Bertin and co-workers. The **pleochroism** of the pyroxenes is so slight that it has been recommended as a test for distinguishing amphiboles from pyroxenes. There is, however, a distinct pleochroism when the coloured diopsides are rotated on the microscope. This subject has been investigated by G. Tschermak.

The **electrical conductivity** of diopside at ordinary temp. is too small to detect.

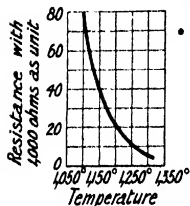

FIG. 103.—The Electrical Resistance of Diopside.

C. Doelter found that at 1478°K. , the conductivity is perceptible, and it increases with rising temp. He found the specific conductivity to be 0.009 mhos at 1340° , and 0.039 mhos at 1366° . There is a marked increase when the mineral melts. The sp. **electrical resistance** curve, with a 1000 ohms as unit, is shown in Fig. 103.

G. A. Kenngott found that diopside, and the green and black augites react strongly alkaline when moistened with water. W. B. and R. E. Rogers discussed the behaviour of diopside with water sat. with carbon dioxide. F. Sestini investigated the action of water at a high temp. A. Daubrée found that steam at 400° decomposes diopside and small crystals of quartz are formed. W. Suida showed

that diopside is not coloured by basic aniline dyes, while more or less weathered varieties are stained. Hydrofluoric acid readily decomposes diopside, but other acids have but a slight action on the mineral, while the aluminous varieties are scarcely unaffected by acids. A. Becker studied the action of hydrochloric acid; C. Doelter, the action of dry hydrogen chloride; W. B. Schmidt, the action of sulphurous acid on diopside; J. Lemberg, the action of soln. of potassium carbonate; and C. Doelter, the action of soln. of sodium carbonate. The weathering of diopside in metamorphic or igneous rocks may produce talc or serpentine, and sometimes epidote; it may furnish amphibole, tremolite, or actinolite. L. Milch showed that carbonates may also be formed. The aluminous diopsides may form chlorite, asbestos, etc. H. Rose described the passage of salite into the *picrophyll* of L. Svanberg—*πικρός*, bitter; *φύλλον*, leaf, in allusion to the odour when moistened. L. Jaczewsky described the transformation of diopside into chrysolite serpentine. The *pitcārantite* of T. Scheerer is a green product from Pitkäranta, Sweden, and is supposed to be derived from diopside or augite. *Traversellite*—*vide supra*—is also derived from diopside; so also is *uralite*. R. van Hise has discussed some of these changes. A. S. Eakle⁹ described a hydrated silicate from the limestone of Crestmore, Cal., with a composition approximating $2(\text{Ca}, \text{Mg})0.2\text{SiO}_2 \cdot \text{H}_2\text{O}$; it may be $\text{H}_2(\text{Ca}, \text{Mg})_2\text{Si}_2\text{O}_7$, or hydrated calcium magnesium dimetasilicate, $2(\text{Ca}, \text{Mg})(\text{SiO}_3)_2 \cdot \text{H}_2\text{O}$. The mineral was called *zurupaite*. It forms compact spheres of soft, silky radiating fibres. The oblique extinction corresponds with monoclinic symmetry. The mineral is easily decomposed by hydrochloric acid, and when moistened it gives no coloration with phenolphthalein. Less than one per cent. of water is given off at 120° , and all is not expelled over Bunsen's flame.

§ 31. Hydrated Magnesium Silicates

A number of ill-defined hydrated magnesium silicates have been reported. J. N. von Fuchs¹ noted that magnesium hydroxide hardens rapidly in contact with a soln. of water-glass, although W. Heldt said that neither the hydroxide nor the calcined oxide suffers any change in contact with water-glass; J. Lemberg, however, said that under these conditions brucite is very slowly converted into a silicate which is gelatinized by hydrochloric acid, and that magnesite in contact with water-glass at 100° for 10 days is partially converted into a silicate.

By adding water-glass to a soln. of magnesium sulphate, W. Heldt obtained a gelatinous mass which, when dried at 100°, had the composition $\text{MgO} \cdot 3\text{SiO}_2 \cdot 2\text{H}_2\text{O}$; and K. Haushofer similarly obtained a product $2\text{MgO} \cdot 7\text{SiO}_2 \cdot 6\text{H}_2\text{O}$. J. Lemberg added to a sat. soln. of magnesium hydrocarbonate an eq. quantity of alkali disilicate soln. and obtained a precipitate approximating, when dried, to $2\text{MgO} \cdot 5\text{SiO}_2 \cdot n\text{H}_2\text{O}$. E. Tischler believed the hydrate $\text{MgSiO}_3 \cdot 2 \cdot 31\text{H}_2\text{O}$ to be a constituent of sand-lime bricks; and he found that this product is obtained by heating a mixture of eq. proportions of silica and magnesia at 8–10 atm. press. in steam. B. von Ammon obtained **hydrated magnesium metasilicate**, a voluminous mass, by adding an excess of crystallized sodium silicate to a soln. of magnesium sulphate. The washed precipitate forms a white opaline mass, which, when dried at 100°, has the composition $3\text{MgSiO}_3 \cdot 5\text{H}_2\text{O}$. The moist precipitate dissolves in hydrochloric acid. Further observations on this subject by A. Gages, J. Lemberg, etc., are indicated below. N. O. Holst claimed to have found white or grey, radiating, crystalline masses with mother-of-pearl lustre, and with a composition corresponding with **dihydrated magnesium orthosilicate**, $\text{Mg}_2\text{SiO}_4 \cdot 2\text{H}_2\text{O}$. He named the mineral *nutricite*. Its sp. gr. is 2.53; and hardness, 3–4. It is attacked by acids. A. S. Eakle found a white radiating fibrous mineral at Crestmore, Jurupa Mts., California, and he called it *jurupaite*. The composition approximated **calcium magnesium dihydro-orthosilicate**, $\text{H}_2(\text{Ca}, \text{Mg})_2\text{Si}_2\text{O}_7$. The crystals are probably monoclinic; the sp. gr. is 2.75; the hardness, 4; the index of refraction parallel with the fibres, 1.576, and perpendicular thereto, 1.568; and the birefringence, 0.007. The water is expelled only at a high temp. The mineral is decomposed by dil. hydrochloric acid without gelatinization.

There is some evidence in favour of the belief that three hydrated magnesium silicates can exist as chemical individuals: namely, *serpentine*, $\text{H}_4\text{Mg}_3\text{Si}_2\text{O}_9$; *meerschaum* or *sepiolite*, $\text{H}_4\text{Mg}_2\text{Si}_3\text{O}_{10}$; and *talc* or *steatite*, $\text{H}_2\text{Mg}_3\text{Si}_4\text{O}_{12}$. There are a few others whose individuality is less well established: *gymnite*, $\text{Mg}_4\text{Si}_3\text{O}_{12}$ —vide deweylite; *aphrodite*, $\text{H}_6\text{Mg}_4\text{Si}_4\text{O}_{16}$ —from *ἀφρός*, foam—of N. J. Berlin, A. Schrauf, and H. Fischer; *spadaite*, $\text{H}_2\text{Mg}_5\text{Si}_6\text{O}_{18} \cdot 3\text{H}_2\text{O}$, of F. von Kobell and others which may be mixtures of magnesium silicates with opaline silica, etc. In nature, the magnesium oxide may be replaced by ferrous oxide, nickel oxide, etc.

It is highly probable that the *λίθος ὀφειτῆς* of Dioscorides' *Materia medica* (5. 161), written about A.D. 50, and the *ophites* of Pliny's *Historia naturalis* (36. 7), published about A.D. 70, referred to a mineral resembling that now known as *serpentine*. The Latin term was translated *serpentine* by G. Agricola;² *Serpentenstein*, *marmor serpentinum*, *marmor zeblicium*, or *lapis serpentinus*, by A. B. de Boodt. Analogous terms were used by J. G. Wallerius, A. Cronstedt, L. A. Emmerling, A. Estner, C. A. Hoffmann, etc., and they have crystallized into *serpentine* in allusion to the green, serpent-like cloudings of the serpentine marble. J. G. Wallerius used the term *lapis colubrinus*. R. J. Haüy regarded serpentine as a rock. In 1759, A. S. Marggraf³ detected magnesia in serpentine; and about the end of the eighteenth or the beginning of the nineteenth century, the mineral was analyzed by R. Kirwan, C. A. Gerhard, P. Bayen, R. Chenevix, J. F. John, V. Hartvall, O. B. Kühn, C. G. Mosander, L. P. Lychnell, F. Stromeyer, etc. A large number of analyses have since been reported.⁴

Serpentine in nature may be associated with many other substances which can

be regarded as impurities. For instance, there may be much ferrous oxide present, and this may be due to admixed ferrous silicate. Serpentine has presumably been formed in nature by the metamorphosis of magnesian silicates—*e.g.* olivine—and it can but rarely be regarded as a one-phase mineral. It is associated with other magnesian silicates as well as ferrous silicates. Ferric oxide and alumina may be present, probably as a result of the serpentinization of aluminous and ferruginous magnesian silicates. There is also a series of analyses with a higher water-content than the normal 13.04 per cent., and another series with a lower water-content. There are also calcareous serpentines; some contain fluorine; and some have up to 10 per cent. carbon dioxide—presumably derived in part from the breaking down of the serpentine itself by carbon dioxide—*vide infra*. In a few cases, the presence of nickel, cobalt, copper, chromium, and manganese oxides has been reported; likewise also the alkalis, sulphates, and phosphates. M. W. Travers found that serpentine from Zermatt contained 0.80 per cent. of hydrogen which was not present in the mineral as an inclusion, but was produced from the non-gaseous constituents by heat, say, $2\text{FeO} + \text{H}_2\text{O} = \text{Fe}_2\text{O}_3 + \text{H}_2$.

The idealized mineral has the composition of a **magnesium tetrahydrosilicate**, $\text{H}_4\text{Mg}_3\text{Si}_2\text{O}_9$. It is assumed that the hydrogen is not present as water of hydration because it is held so tenaciously when heated—*vide infra*. R. Brauns represents its formula $\text{Mg}(\text{MgOH})_2\text{H}_2\text{Si}_2\text{O}_7$. J. Jakob applied the co-ordination theory and represented it by

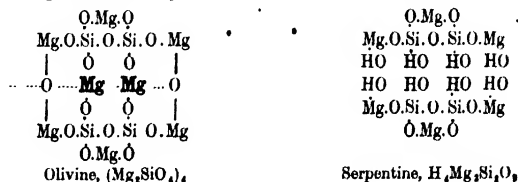

F. W. Clarke, and F. W. Clarke and E. A. Schneider regarded serpentine as a derivative of a polymerized magnesium orthosilicate, $\text{Mg}_4(\text{SiO}_4)_2$, namely, $\text{Mg}_2(\text{SiO}_4)_2\text{H}_3(\text{MgOH})$. The assumption that some magnesium is present as hydroxide fits observations on the ultra-red transmission spectrum—*vide infra*. S. Hillebrand regarded serpentine as a salt of the acid $\text{H}_4\text{Si}_2\text{O}_9$; and chrysotile as a salt of the acid $\text{H}_{10}\text{Si}_4\text{O}_{13}$. He considers these two minerals to be related with olivine as:

He represented serpentine and chrysotile by the formula $\text{Mg}_6\text{H}_8\text{Si}_4\text{O}_{18}$, and considered them to be isomeric forms of the same silicate. G. Tschermak,⁵ and R. Scharizer showed that the serpentine formula can be represented in two ways—one symmetrical and the other unsymmetrical:

The genesis of serpentine has been investigated by A. Quenstedt, M. Websky, etc. The general result shows that serpentine may be formed from any silicate rich in magnesia—*e.g.* olivine, pyroxene, amphibole, garnet, etc. It can also be produced by the action of percolating magnesian waters on minerals like the feldspars, which are non-magnesian. G. Tschermak represents the transformation of olivine into serpentine by the equation: $2\text{Mg}_2\text{SiO}_4 + \text{CO}_2 + 2\text{H}_2\text{O} = \text{H}_4\text{Mg}_3\text{Si}_2\text{O}_9 + \text{MgCO}_3$; and of diopside $3\text{MgCa}(\text{SiO}_3)_2 + 3\text{CO}_2 + 2\text{H}_2\text{O} = \text{H}_4\text{Mg}_3\text{Si}_2\text{O}_9 + 3\text{CaCO}_3 + 4\text{SiO}_2$. R. Scharizer represents the serpentinization of olivine by the structural formulæ:

The carbonated water attacks the magnesium atoms indicated in the above formula, forming magnesium carbonate. The olivine mol. simultaneously splits into two parts; each part furnishes a mol. of serpentine. Compare this with the formation of talc—*vide infra*. Similarly, also in the serpentinization of a pyroxene or amphibole:

V. Iskyul said that the serpentines are metasilicates, and compact serpentine and chrysotile are pyroxene silicates similar to enstatite, while antigorite is similar to anthophyllite. The colloidal origin of the minerals of the serpentine family has been discussed by F. Cornu. A. Gages claimed to have made serpentine as a transparent amorphous mass by allowing gelatinous magnesium silicate to remain in contact with dil. potash-lye for some months. J. Lemberg also made a serpentine by the action of a soln. of sodium silicate on magnesite for 10 days at 100°, by heating in a sealed glass tube monticellite with a soln. of magnesium chloride for 18 hrs.; and in other ways.

Serpentine may occur massive, lamellar, foliated, fibrous, and crystalline. Serpentine as a rock may constitute whole mountains, and it is then associated with dolomite, magnesite, calcite, etc. The variety which makes a clouded green sometimes with white or pale green veins furnished the *vert antique* or *ophiolite* of the ancients. It is used for interior decorative work, but if exposed outside, it soon tarnishes by weathering. Some varieties take a high polish, and can be turned in a lathe, making ornaments of various kinds. The so-called *precious* or *noble serpentine* is a rich green of various shades, and more or less translucent. G. P. Merrill called a banded serpentine from Mexico, *ricolite*—from *rico*, in allusion to its rich green colour.

The texture of serpentine can thus be very varied; many of the varieties have received special names. G. T. Bowen* described what he regarded as a massive and granular nephrite, and J. D. Dana called it *bowenite*. J. L. Smith and G. J. Brush proved it to be serpentine. A massive serpentine, yellow to green in colour, was described by T. Thomson and named *retinalite*—from *πῑρῑν*, resin—in allusion to its waxy or resinous lustre. It is thought to be a mixture of serpentine and deweylite. T. S. Hunt regarded it as compact serpentine. G. A. Kenngott described a brown or greenish-black variety which he named *vorhauerite* after J. Vorhauser. A. des Cloizeaux regarded it as a compact serpentine. J. D. Dana called a variety resembling compact lithomarge *porcellophite*, and this is possibly the meerschau of Taberg and Sala, Sweden. The *antigorite* of E. Schweizer is a thin lamellar variety from Antigorio Valley, Piedmont. It was also studied by G. J. Brush, and by G. A. Kenngott. V. Iskyul investigated the action of hydrochloric acid. A lamellar apple-green variety from Texas was named *williamsite* by C. U. Shepard; it was shown by B. Hermann, and by J. L. Smith and G. J. Irish, to be serpentine. T. Nuttall described a thin foliated variety from Hoboken, New Jersey; and he called it *marmolite*—from *μαρμαίρω*, I shine—in allusion to its pearly and somewhat metallic lustre. L. Vanuxem, and F. A. Genth and G. J. Brush showed that it is a foliated serpentine. J. R. Blum's marmolite was shown by A. Breithaupt to be a variety of mica. A. E. Nordenskjöld found a scaly variety of serpentine at Hopansuo, Finland, which exfoliated when heated, and which was hence named *thermophyllite*—*θερμῑ*, heat; *φύλλον*, a leaf.

F. von Kobell applied the name *chrysotile* to a delicately fibrous serpentine from Reichenstein, in Silesia. It is named from *χρῑσῑδῑς*, golden; *τίλος*, fibrous. Its colour is greenish-white, green, yellow, and brown. According to J. F. Hausmann, the term includes most of the silky *amantius* or schiller asbestos of serpentine rocks. V. Iskyul examined the action of hydrochloric acid on chrysotile. J. F. Hausmann applied the term *picrolite* to a fibrous and columnar variety of serpentine from Taberg, Sweden. The term is derived from *πικρῑς*, bitter, in allusion to its containing bitter-earth or magnesia. It was studied by F. Stromeyer, L. P. Lychnell, M. Websky, R. Brauns, C. List, C. Alnroth, etc. The *ballinmorite* of T. Thomson was shown by C. F. Rammelsberg to be a chrysotile; and R. Hermann, G. A. Kenngott, and C. von Hauer described impure varieties. L. F. Svanberg's

hydrophile—named in allusion to the water present—is a dark green fibrous serpentine from Taberg, Sweden. H. Fischer found it to be impregnated with magnetite. M. Websky regarded it as a ferruginous metaxite. A fibrous greenish-black crust, found by C. U. Shepard on the magnetite of Monroe, New York, was named *jenkinsite*, after J. Jenkins. It was shown by J. L. Smith and G. J. Brush to be a form of hydrophile. A. Breithaupt described a silky fibrous mineral from Schwarzenberg; and he named it *metaxite*—from *μετάξω*, silk. A. Delesse, R. Brauns, and M. Websky showed that it is a fine-fibred serpentine. A. E. Arppe, K. Hallsten, F. J. Wiik, and G. A. Kenngott have examined the mineral. A. E. Arppe's *microfluite* proved to be a mixture of fluorite, magnetite, and metaxite.

A. Frenzel obtained a serpentinous mineral from Zöblitz, Saxony, and hence termed *zöblitzite*. It was also described by C. F. Rammelsberg. R. Brauns described the mineral *radiotite* from Wallenfels, Nassau; and named on account of its radial structure. R. Brauns named a serpentinous mineral from Amelose, Hessen, after M. Websky, *webskyite*. It was also studied by F. Cornu, and is probably an alteration product of serpentine. The mineral *limbachite*, from Limbach, Saxony, was shown by A. Frenzel to be an aluminous serpentine. F. P. Dunnington obtained a similar mineral from Webster, N. Carolina. A. Schraut described the mineral *enophite*, from Kiemze, Bohemia, as a chlorite-like serpentine. A. Breithaupt obtained from Waldheim, Saxony, a green massive mineral with a resinous lustre; he called it *dermatine*—from *δέρμα*, skin—in allusion to its occurrence as an incrustation on serpentine. It is probably colloidal. M. F. Heddle obtained a fawn-coloured serpentinous mineral from Totaig, Scotland, and hence he called it *totaigite*. W. Haidinger described a mineral from Engelsberg, Bohemia, which he named *pirocennane* from *πικρόν*, bitter; *ὀσμή*, odour. It has some relationship with talc, and W. F. Foshag classes it with the talcs. It was discussed by G. Magnus, A. Frenzel, H. Fischer, and C. F. Rammelsberg. M. F. Heddle found in various parts of Scotland a kind of mountain cork or mountain leather as *pilolite*—from *πίλος*, felt. Its composition corresponded with $4\text{MgO} \cdot \text{Al}_2\text{O}_3 \cdot 10\text{SiO}_2 \cdot 15\text{H}_2\text{O}$. J. Henderson also described a specimen from New Zealand. C. U. Shepard found a serpentinous substance which he called *pelhamite*—*pelhamite*—in the asbestos mine of Pelham, Mass. N. Nordenskjöld described a serpentinous mineral from Zermatt, Schweiz (Switzerland), and he called it *zernattite*, while A. von Forsmann called it *schwizerite*. A. Breithaupt found a mineral in Frankenstein, Silesia, which he named *cerolite* from *κνρόν*, wax—in allusion to its vitreous, resinous appearance. It was also described by O. B. Kühn, R. Hermann, and F. A. Genth. F. Fock called a variety from Zillertal, Tyrol, *meinaphyllite*; it contained 2 per cent. of soda.
